Brookhaven National Laboratories, Upton, NY 11973, U.S.A.

Methods are presented for calculating the energy required, directly and indirectly, to produce all types of goods and services. Procedures for combining process analysis with input-output analysis are described. This enables the analyst to focus data acquisition effects cost-effectively, and to achieve down to some minimum degree a specified accuracy in the results. The report presents sample calculations and provides the tables and charts needed to assess total energy requirements of any technology, including those for producing or conserving energy.

1. Introduction

When we consume anything, we consume energy. It takes energy to manufacture, deliver and sell all types of goods and services. It is possible to add up the energy required at each step of the production process to determine the total 'energy cost' of particular goods and services.

The concept also applies to facilities that produce or conserve energy. It takes energy to construct and operate oil wells and pipelines, and this should be compared to the energy output. Similarly, it takes energy to manufacture insulation for homes and additional capital equipment for industry; these energy costs can also be compared to the energy savings.

Consumers demand energy in two ways; directly and indirectly. Energy is consumed directly in the form of gasoline, electricity, natural gas, or fuel oil. It is consumed indirectly as energy used elsewhere in the economy to

*This work was supported by the US Energy Research and Development Administration. We wish to express our thanks to Donna Amado who was responsible for the computer programming and to Charles R. Mandelbaum of E.R.D.A. for helpful comments on an earlier draft of the manuscript.

produce the other goods and services purchased by consumers. Indirect energy is by no means negligible; the average consumer demands more energy indirectly than directly [Herenden and Tanaka (1975)].

To clarify the concept of energy cost, consider aluminum as an example. A certain amount of energy is consumed directly in the ore reduction process. But energy is also required to mine the bauxite and transport it to the smelter. Additional energy is needed to manufacture the mining and transportation equipment, and to make the inputs to these industries. All these energies have to be summed to determine the total energy cost of aluminum.

The purchase of this report is to provide a practical guide for calculating the energy cost of any item. Two methods are described. One is tedious and involves adding all the energy inputs individually and is subject to error because some inputs are inevitably neglected. The other is a simpler one-step operation that has inaccuracies due to the level of aggregation at which goods and services are defined. We describe both methods, and then show how to combine them to minimize the effort required to obtain a predetermined degree of accuracy in the result. Appendix A gives most of the data needed for any application.

The range of possible applications is quite broad. Energy analyses have been used to determine the overall energy efficiencies of systems as varied as beverage containers [Hannon (1973)] and nuclear power plants [Rotty et al. (1975)]. Published results of energy analyses (particularly net energy analyses) vary for a host of reasons, due to differences in computational techniques, system boundaries, types of fuels and energy, etc. [Bullar and Herenden (1974), Pilata (1977)]. This report is limited to treating the computational issues involved in such analyses. The methods and results presented are consistent with a forthcoming set of ERDA guidelines for net energy analysis [Perry (1977)].

1.1. *Definitions and conventions*

The data and methodologies described in this report permit calculation of five types of energy 'embodied' in a particular goods or service. One calculation determines the coal required, directly and indirectly, to produce a unit of aluminum. Parallel calculations yield the total crude oil and gas, refined oil, electricity, and natural gas requirements. All these inputs are useful for certain purposes, but they are not directly additive to obtain a 'total energy requirement'. For example, due to the direct plus indirect nature of the calculations, there would be some double counting of electricity and the coal used to produce electricity.

To obtain a total energy figure, we adopt the convention employed historically by the U.S. Bureau of Mines to combine U.S. fuel and electricity consumption. This convention views coal, crude oil and crude gas as *primary*

fossil energy resources, and expresses physical quantities (tons, barrels, cubic feet) in terms of their total enthalpy.¹ Similarly, hydro and nuclear electricity are viewed as primary energy resources, whose enthalpies are evaluated in terms of their fossil fuel equivalents using the prevailing heat rate for fossil electric power plants. These enthalpies are then added to define a total primary requirement, and double-counting is avoided.

Similarly, we define a total primary energy *intensity* as the energy required directly and indirectly to produce a unit of goods or services for final consumption. It is calculated by adding the (direct plus indirect) coal intensity, crude oil and gas intensity, and the fossil fuel equivalent of the hydro and nuclear electric intensity. It is useful to compare the total energy intensities of goods and services for broad-based analyses of conservation options, such as substituting fiberglass for steel in a manufacturing process. In specific instances where options for fuel substitution are limited (e.g., aluminum production), it is more useful to retain the individual fuel intensity detail. In particular, *net* energy analyses often require that the distinction between fuels be maintained, because the object of the analysis is often a facility (e.g., a power plant) for converting one form of energy to another. 'Viewing all energy as equal' obscures the economic purpose of the facility [Bullard (1976), IES report (1975)].

2. Methodology

2.1. General

The energy cost of any economic activity can be measured by either of two general methods: Process analysis or input-output (I-O) analysis. As will be shown, both theoretically require the same data and would yield the same result if a fully disaggregated data base were available. In the real world, each technique is most useful for a particular type of problem. Aggregated, nationwide problems are well suited to I-O analysis because the data base for this analysis is a 368-sector model of the entire U.S. economy. Process analysis is more suited to specific processes, products, or manufacturing chains for which physical flows of goods and services are easy to trace.

2.2. Process analysis

Process analysis begins by identifying one particular product as the object of study. This *target product* may be either a good or a service. One then examines the process which makes the product and asks: 'What goods and

¹For the types of energy considered here, total enthalpy is approximately equal to Gibbs' free energy. The latter is viewed by many as the 'ultimate' measure of energy consumption because it is truly consumed and cannot be recycled. For practical purposes in these calculations, the two are equal.

services were required directly by this plant to produce the target product? When the list of such inputs is obtained, it will include some fuels (direct energy) and some non-energy goods and services from other industries. The direct energy use is tallied while each non-energy input is further examined to determine the energy and non-energy inputs required for its production. This process continues, tracing back from the target product through each stage of the production process (fig. 1). Each successive step in the analysis typically identifies smaller and smaller energy inputs, and all these energy inputs are summed to obtain the total energy *intensity* of the target product. The first energy input is called the *direct* energy requirement, the remainder is called the *indirect* energy requirement. It is often the case that certain items appear as both inputs and outputs several places in the production tree, reflecting feedback loops of economic activity.

In stage 2 and beyond, the indirect energy inputs are identified and summed. Note that indirect energy inputs include the energy consumed in energy producing industries.

In fig. 1, there are four inputs to the production of the *target product*. Suppose input *A* is energy and *B*, *C*, and *D* are non-energy goods and services. The *direct* energy requirement is simply input *A*. *Indirect* energy inputs to the target product are the sum of energy inputs to all the production processes in stages 2, 3, and beyond.

In practice, a large number of terms is never computed, and the analysis is terminated at a point where the input is believed to add a negligible amount to total energy use. At the second stage only the most significant inputs are considered, and of those, only a subset is further broken down into its components. Unfortunately, diminishing contributions from each stage provide no guarantee that the truncated infinite number of terms actually sum to a negligible quantity.

Performing a process analysis requires extensive data on the production of the target product and similar (but usually less detailed) data on any secondary, tertiary, and other inputs not truncated. For aggregated production sectors, data are obtained from government statistics on economic activity. For individual production processes, information must often be collated directly from manufacturers, trade associations, and consultants. If all flows can be measured in physical units, there is usually no reason to introduce dollar values in the analysis, so the resulting energy intensity is expressed in physical terms (energy/unit of target product).

As an example we shall calculate the energy intensity of cars in a simple 3-sector economy.² This hypothetical economy consists only of energy, measured in British Thermal Units (Btu), cars and another aggregate industry

²The Batelle/Columbus Labs (1975) and Larry Teasley (1974) provide excellent examples of practical process analysis.

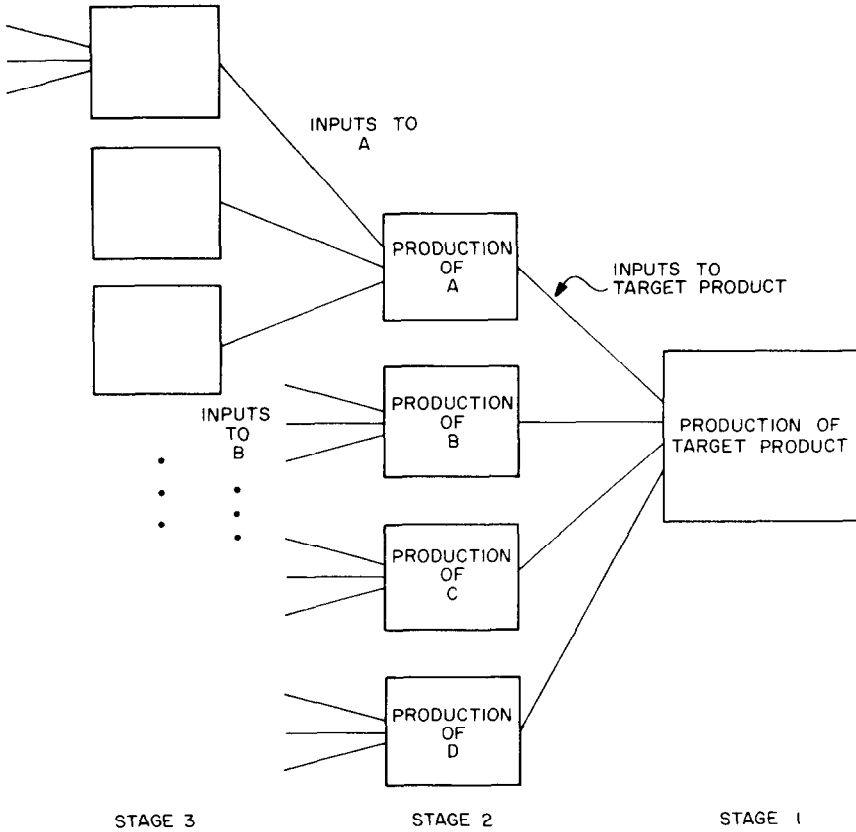

Fig. 1. Successive stages in a process analysis.

composed of all other goods and services. We shall simply label this aggregate industry 'goods' and presume its output is measured in dollars due to the heterogeneity of its output. Assume that census data for all three sectors in this hypothetical economic system identify the inputs for each industry's production process. A typical production facility in the car industry uses 0.6 car, 0.01 Btu energy and \$0.25 worth of goods to produce one car. (In this entire example, the numbers are chosen arbitrarily.) The final stage of production is shown in fig. 2.

Fig. 2. Production of cars.

Similarly, typical energy and goods production facilities use inputs as shown in figs. 3a and 3b. Energy extracted from the earth does not appear in fig. 3a, only purchased energy inputs are shown.

We now have most of the data necessary to calculate the energy intensity of cars using process analysis. The production 'tree' is shown in fig. 4, where dashed lines denote inputs that are ignored, and represent the truncation points for the analysis. Values for input flows exactly match figs. 2 and 3 in the first production stage where the output is one unit. Outputs at all other stages are less than one unit and their inputs are scaled accordingly. For example, in the second stage, 0.6 cars are produced, so scaling the inputs in fig. 2 gives $(0.6)(0.01)$ Btu, $(0.6)(0.6)$ cars, and $(0.6)(0.25)$ \$ goods.

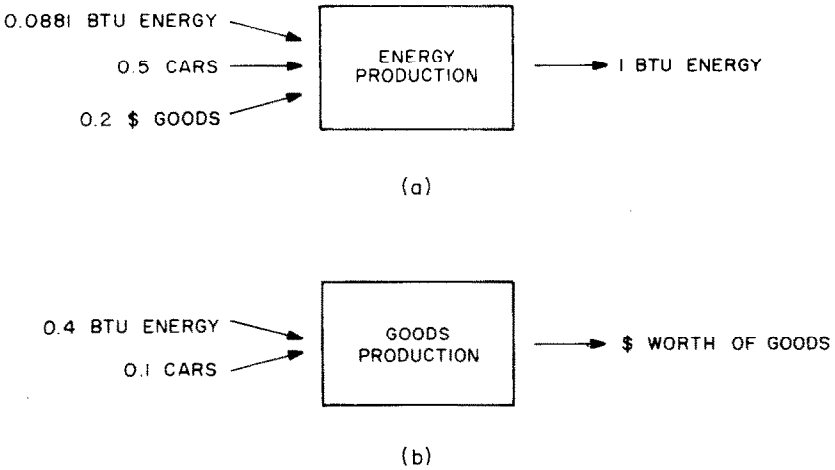

Fig. 3. Production of energy and goods.

In fig. 4, the *direct*³ energy input to car production is 0.010 Btu/car. There are an infinite number of indirect inputs, all but three of which are neglected. They sum to $0.006 + 0.100 + 0.036 = 0.142$ Btu/car. Thus process analysis yields a total (direct plus indirect) energy intensity of 0.152 Btu/car. The truncation error is unknown.

In this simple 3-sector example it is clear that we have sufficient data to carry the process analysis on for an indefinite number of steps. In a real problem, however, a process is truncated to reduce the data acquisition effort. For example, in an economic system with hundreds of sectors, a process analyst may follow only the largest branches on the tree to limit data

³Also called 'first round' energy cost.

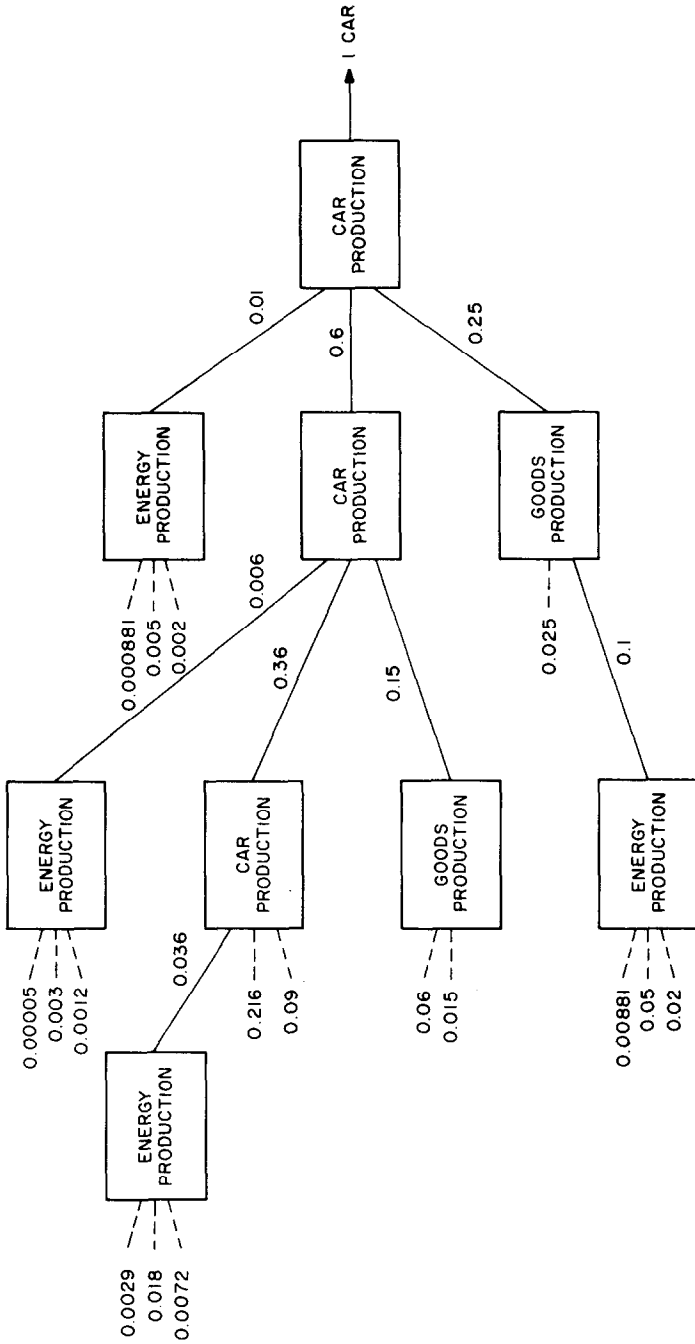

Fig. 4. Hypothetical 3-sector process analysis.

acquisition efforts to those sectors most important to the particular target product.

In table 1, the inputs shown in figs. 2 and 3 are arranged in matrix form, normalized to one unit of output. This matrix is one way to represent the technologies for all goods and services in our hypothetical economy. Note that it shows only *interindustry* flows, not resource flows from Earth to producing industries.

Table 1
Specification of production technologies.

Input ↓ to production of →	Energy	Cars	Goods
Energy	0.0881 Btu/Btu	0.01 Btu/car	0.4 Btu/\$
Cars	0.5 Cars/Btu	0.6 Cars/Car	0.1 Cars/\$
Goods	0.2 \$/Btu	0.25 \$/car	0 \$/\$

Fig. 5. Energy balance for a producing sector.

Entries on the diagonal show the amount of self-input required to produce 1 unit of output. For example, each Btu of energy output requires 0.0881 Btu of energy input. This representation of the data, as we shall see below, is useful for input-output analysis.

2.3. Input-output analysis

Input-output analysis is a modeling technique used extensively in economic research since its introduction by Leontief (1941). It has been adapted to analyze energy and labor intensities [Herendeen and Bullard (1974)]. The structure of the model, a large linear network, remains the same for any variable. Initially the economy must be disaggregated into N major sectors, each producing a unique good or service and each characterized by a node in the network equations. Examples of these sectors might be primary metals, retail trade or petroleum products. Fig. 5 shows the energy flows entering and leaving each sector.

Energy 'embodied' in outputs from other sectors enters at the left and can be expressed as $v_i T_{in}$, energy intensity of product i times the input of sector i

to sector n . Energy embodied in the sector's output is shown exiting at the right and is expressed as the product of the energy per unit of sector n output (ε_n) and its output (X_n). If in fig. 5, sector n denotes the energy sector, a non-zero amount E_n is extracted from the earth. The energy balance equation becomes

$$\sum_{i=1}^N \varepsilon_i T_{in} + E_n = \varepsilon_n X_n, \quad (1)$$

or, in matrix notation we have

$$\varepsilon \mathbf{T} + \mathbf{E} = \varepsilon \hat{\mathbf{X}}. \quad (2)$$

The above set of N equations can be solved for the N unknowns, ε . $\hat{\mathbf{X}}$ is the diagonal matrix whose elements represent the total output from each sector.

For a typical product, n , the production technology is represented by a vector \mathbf{A}_n where a typical element A_{in} represents the amount of product i needed directly to produce a unit of product n . The $N \times N$ matrix \mathbf{A} then provides a linear representation of the technology of producing all goods and services. From this definition of \mathbf{A} we have

$$\mathbf{T} = \mathbf{A} \hat{\mathbf{X}}, \quad (3)$$

and eq. (2) becomes

$$\varepsilon = \mathbf{e}(\mathbf{I} - \mathbf{A})^{-1}, \quad (4)$$

where \mathbf{e} is a unit vector which identifies the energy sector row of $(\mathbf{I} - \mathbf{A})^{-1}$ as the *energy intensities*.⁴ For a multi-fuel economy, this analysis can be repeated for each type of energy (coal, oil, etc.) and the total primary energy intensities can be calculated [Herendeen and Bullard (1974)].

Though I-O is a simple and elegant technique, it would hardly be useful without large amounts of data. The U.S. Department of Commerce has reported economy-wide data separated into 368 sectors of economic activity for 1963 and 1967. From these data, the \mathbf{A} (technological coefficients) and $\hat{\mathbf{X}}$ (total output) matrices are determined. Physical data for the \mathbf{E} (energy) vector are available from a variety of sources and are equal to the output, X_n , of the primary energy-producing sectors. Thus, eq. (4) can be solved for an ε (energy intensity) vector containing 368 values for the entire economy in the year studied.

⁴This unit vector appears algebraically because $E \equiv X$ for the energy sectors: their output defined to equal what they extract from the earth.

This pure I-O approach implicitly assumes that the target product is *typical* of a certain sector's output. (The same assumption was made for 'cars' in the process-analysis example.) Treatment of atypical products is discussed in section 2.3.2.

2.3.1. A simple I-O example

Now we consider a practical application of input-output analysis. It makes use of a 357-sector description of the U.S. economic system in 1967. It includes detailed information on consumption of five forms of energy by each sector, and is based on data from the U.S. Bureau of Mines and the U.S. Department of Commerce Bureau of Economic Analysis (BEA).

In this example we shall calculate the energy cost of a *typical* large computer. We assume that the price (to the ultimate consumer) was \$1,000,000 in 1970. The first step is to determine which of the 357 BEA economic sectors produces computing machines. Reference to the table of the Industry Classification in the 1967 Input-Output study shows that the correct sector is 51.01, 'computing and related machines'. The table also lists the SIC (Standard Industrial Classification) industries included in BEA sector 51.01. Thus for a more detailed description of 51.01, one could check either the results of the Office of Statistical Standards (1967) or those of the U.S. Department of Commerce (1970) to insure that the correct sector is used.

Having identified the appropriate sector, the corresponding energy intensity can be obtained from table A-4, and it is multiplied by the quantity of computers to obtain the total energy cost. The total primary energy intensity given in the table is 47,116 Btu per 1967 dollar's worth of computers. The Department of Commerce data used to construct the I-O tables in 1967 measured that sector's output in dollars because of the aggregation within the computer industry; that is why the energy intensity is given in those terms. This is true for all non-energy sectors in the U.S. input-output tables; only the five energy sector outputs are expressed in physical units (Btu).

However, due to inflation between 1967 and 1970, there is a difference between one million 1967 dollars' worth of computers and one million 1970 dollars' worth, even though we're talking about exactly the same machine. If we convert the \$1 million price tag in 1970 to 1967 prices, we can remove the effects of inflation, and the '1967 dollars' unit of measurement becomes a surrogate for a physical unit of measurement.⁵ Using price indices (deflators)

⁵Note that if we were to use purely physical units we could avoid the problems of dollar cost deflation. If physical quantities are known, these can often be energy-costed directly. The energy intensities in table A-4 can be converted to (Btu/physical unit) using the 1967 implied prices of many goods and services. For a few additional materials, energy costs/physical unit are given by Perry (1977).

from table A-1 we calculate the quantity of computers in units of 1967 dollars:

$$\begin{aligned} & \text{Value of a million dollar (1970) computer in 1967 dollars} \\ &= \$10^6 \frac{(\text{1967 price index for 51.01})}{(\text{1970 price index for 51.01})} = (10^6) \frac{1.0}{1.015} \\ &= (10^6) 0.99 = \$990,000 \text{ (1967)}. \end{aligned}$$

This figure is multiplied by the total primary energy intensity (ϵ) for sector 51.01, found in table A-4,

$$\begin{aligned} & \text{Energy cost of computer} \\ &= \$990,000 \text{ (1967)} \times 47,116 \text{ Btu}/\$1967 \\ &= 46.64 \text{ billion Btu}. \end{aligned}$$

This example demonstrates how energy costs can be found quite simply using I-O. However, anyone employing this method should have a good understanding of the limitations and uncertainties inherent in it.

2.3.2. *Uncertainty associated with I-O analysis*

One source of uncertainty which has been mentioned already is the change in price levels over time. Due to inflation, price levels change while physical quantities (and energy cost) may not. Price level changes can be approximately corrected using deflators as above, though deflators are sometimes inaccurate and may not strictly conform to BEA sector definitions. Measuring quantities in terms of constant (1967) dollars is a surrogate for using physical units. For some products the correspondence between physical units and 1967 dollars is known. The average 1967 price data in table A-5 can be used to express many energy intensities directly in terms of Btu per physical unit.

Another source of uncertainty is change in the structure of the economy, the technology of producing goods and services, as represented by the matrix A. Energy intensities are a function of A alone, and as technological change occurs over time, the uncertainty in ϵ will increase. Recent studies have identified the parameters in A which are most important for energy analysis and work is now underway to update them to reflect the latest technological advances [Bullard and Sebald (1975)].

Some of the uncertainty in ϵ is due to sector aggregation. Ideally, each product would be a unique output of a BEA sector, and therefore would have a unique energy coefficient. Because millions of different goods and

services are produced by the U.S. economy, it would be infeasible to collect data on N^2 technological coefficients at that level of detail. In practice, many similar products or services with a range of energy costs are grouped in a single sector. The question one wants to ask prior to calculation is: How much of BEA sector X is devoted to making the target product X_1 ? To answer this question, it is possible to go back to the original Department of Commerce data base and examine the composition of each sector. We have done this and list in table A-5 some common BEA sectors and their major products.⁶ To the extent that the target product is typical of the sector's output, the sector energy intensity is a relatively accurate measure of its

Table 2
Energy cost of a computer.

Sector	% of purchase price (table A-3)	Allocated share of total cost (\$1970)	Deflator (\$1967/\$1970) (table A-1)	Energy intensity Btu/\$1967 (table A-4)	Primary energy cost (10^9 Btu)
65.01–65.06	0	—	—	—	—
69.01	5	\$50,000	0.91	39,636	1.8
69.02	1	\$10,000	0.84	39,372	0.3
51.01	94	\$940,000	0.99	47,116	43.8
Total		\$1,000,000			45.9

energy cost. This table provides a basis for estimating the certainty in an energy intensity, as applied to a particular product. If the target product were a very minor output of a large or diverse sector, there is little the user can do to correct the error using input-output analysis. There is a way to eliminate this problem, and it will be discussed in section 2.4.

A number of economic and accounting conventions also cause problems. Since data are collected from firms rather than consumers, they are based on the firm's value of the product, or producer's price. However, consumers pay not only this price but also the wholesale and retail margins, transportation costs, insurance, etc., required to market the product. In the previous example of the energy cost of the computer, these margins were ignored. Taking them into account, the calculation proceeds as follows:

The total price (to the purchaser) of the computer is \$1,000,000 in 1970. Of this, the margins can be obtained from tables A-2 and A-3, and a more

⁶Sectors listed are those producing major inputs to construction and operation of facilities for energy production, processing and transportation.

accurate energy cost can be determined as set forth in table 2. This result compares to 46.64×10^9 Btu in the previous example where the margins were not explicitly accounted for. The favorable comparison is fortuitous in this example because the energy intensity of computers happens to be approximately equal to that of trade. For a more energy-intensive commodity (e.g., steel), the impact of including margins explicitly could be quite significant.

Another economic convention is that purchases of capital goods are counted as net outputs of the economic system, rather than as inputs to production processes. This means that ordinary I-O energy intensities [Bullard and Herendeen (1974)] do not include the energy required to build the factories or machines used by each sector. A correction⁷ has been performed using capital requirements data from Fisher and Chilton (1971), so the energy intensities presented in table A-4 include the energy required to make capital equipment.

Finally, there is uncertainty in the results due to errors in collecting and processing the basic data on the technology of producing goods and services. These errors include those due to, more specifically, incomplete census coverage, reporting errors due to misunderstanding, false reports, sampling errors inherent in surveys of firms, transcription or key punching errors, the possibility that forms are lost, classification errors, and the problems of separating companies from establishments in processing returns from surveys or census. Considerable effort has been expended in trying to estimate these stochastic errors, and their effect on the resulting energy intensities. Our investigation considered all the sources of error listed directly above including incomplete reporting. Briefly, results indicate that the energy intensities are approximately normally distributed with more than a 99% likelihood that the actual value falls within the error bounds shown in table A-4 [Bullard (1976)]. It is assumed that these values, computed at the aggregated 90-sector level, can be applied directly to the 357-sector intensities. However, these figures do not include uncertainty due to changes in the technology of producing goods and services since 1967. Where significant process changes have been made, the error bounds should be increased.

Table 3 summarizes the error treatment in energy input-output analysis and points to two errors that are unresolvable using this technique.

The last two items in table 3 result from the fact that the U.S. input-output tables are aggregated to such a level that it is not possible to express each sector's output in terms of a single physical unit, and the data are collected on establishments not directly on processes. Methods for eliminating these problems are discussed by Herendeen and Bullard (1974).

⁷This correction is described by Putnam et al. (1975). Since capital data were only available at the 90-sector level of detail, it was assumed that individual processes within those categories are equally capital-intensive.

Table 3
 Limitations of input-output analysis.

Problem	Treatment
1. Price level changes	Use tables A-2 and A-6
2. Technology changes (since base year)	Updated energy intensities not yet available
3. Aggregation: Typical and atypical products	Use table A-6
4. Producer's versus purchaser's prices	Use tables A-3 and A-4
5. Including energy cost of capital	Use table A-5
6. Uncertainty in base year data	Use table A-7
7. Physical flows assumed proportional to dollar values	Use a more disaggregated model
8. Errors due to secondary products and linearity assumptions	None

2.4. Combining process and input–output analyses

As shown above, the energy cost of any good and service can be determined by either process analysis or input–output analysis. In theory, both methods require identical input data and provide identical results.

For most applications, however, the complete set of input–output data (the $N \times N$ matrix A) are not available at the necessary level of detail. It exists only at a more aggregated level of about 368 sectors for the United States economic system, and is much smaller for most other nations.

Because of this lack of data, input–output results give only the *average* energy intensity of a sector's output. Accuracy is limited by the level of aggregation: the energy intensity of aluminum castings would apply to both pressure cookers and aluminum tools because both are included in sector 38.11. Process analysis does provide a framework for determining the energy intensity of atypical products within a sector. The chain of inputs can be traced back to the point where all inputs are sufficiently 'typical' or until the inputs are so small that the aggregation error is tolerable.

The errors associated with truncating a process analysis can be minimized using the results of input–output analysis. The truncation error is replaced by a smaller aggregation error associated with energy-costing the higher indirect order inputs. The combination of these techniques is called 'hybrid analysis' and the procedures are described below.

Theoretically, each step in a process analysis may be viewed as an expansion of the system boundary (around the item being analyzed) into the economic system, tabulating direct energy inputs at each step (see fig. 6). *The results of input–output analysis may be used to estimate the energy embodied in flows crossing the system boundary at any level, by associating each good or service with one of the 368 sectors of the I–O model.* These I–O results are indifferent to the location of the system boundary. Regardless of the number of process analysis steps taken, the boundary looks the same from the I–O side. Thus in theory, it does not matter at which stage of the process analysis you correct for the truncation error. In practice, by carefully choosing the number of stages, hybrid analysis can reduce the error in both techniques and produce the most accurate result possible. The truncation error is eliminated from the process analysis and the aggregation error is minimized in the I–O analysis.

2.4.1. Procedure

To perform a hybrid analysis, begin by doing the first one or two steps in a process analysis. Select the target product and carefully determine the energy and materials required for its production. Some of the input materials may be typical products of I–O sectors; I–O can be used to determine their

total energy costs with only a single additional calculation. Thus the only input materials requiring further process analysis are atypical products not easily classified in an I-O sector. The technology for producing these items must be examined to identify their inputs which must in turn be energy-costed with either I-O or further process analysis, depending on whether they are typical or not. Hybrid analysis is best suited for large atypical problems such as determining the energy cost of a power plant, since there is no I-O sector corresponding to power plant construction.

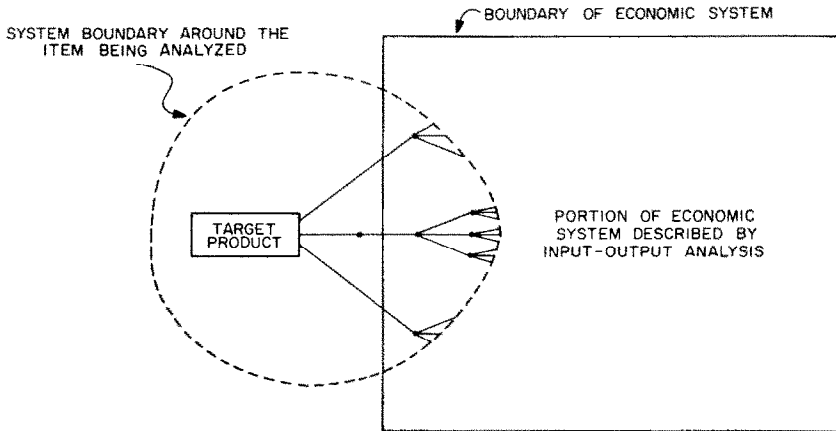

Fig. 6. System boundaries for process and input-output analyses.

2.4.2. Example

We will now calculate the energy cost of a large prototype coal-fired power plant [Pilati and Richard (1975)]. Assume that information on this plant is available from either a line-item plant budget or an expert consultant on the project. Our objective is to calculate this energy cost in the easiest manner within an uncertainty of $\pm 10\%$. A sequence of approximations will be used, starting with the simplest assumptions. The sequence can be terminated as soon as the error tolerance is less than 10% .

As a first approximation, we could multiply the dollar cost of the power plant (\$88 million⁸ at 1970 prices, $\pm 15\%$) by the average intensity for all

⁸This is the cost of all purchased inputs to power plant construction—materials, services, etc. Wages and taxes are excluded to be compatible with the system boundary of the I-O model which corresponds to GNP [see Bullard (1976)]. Using this convention, energy to produce items bought with wages are charged to the wage earner, not the employer.

goods and services in 1970 (68,690 Btu/\$).⁹ This coefficient is simply the ratio of total U.S. energy use to gross national product in 1970. When used to approximate the energy intensity of a particular item such as a power plant, this coefficient has an extremely large uncertainty (say a factor of two: +100%, -50%). The total energy cost and error terms are given by the formula

$$(a \pm \Delta a)(\varepsilon \pm \Delta \varepsilon) = a\varepsilon \pm a\Delta \varepsilon \pm \varepsilon\Delta a \pm \Delta \varepsilon\Delta a,$$

where a is the budget figure and ε the energy intensity, and Δa and $\Delta \varepsilon$ represent the uncertainties. Values for Δa and $\Delta \varepsilon$ are obtained by simply multiplying a and ε by their respective percentage errors. This first approximation yields an energy cost of 6.04×10^{12} Btu, while the first-order errors are clearly far outside the desired tolerance interval,

$$+(\varepsilon\Delta a) + (a\Delta \varepsilon) = +6.9 \times 10^{12} \text{ Btu (+114\%)},$$

$$-(\varepsilon\Delta a) - (a\Delta \varepsilon) = -3.9 \times 10^{12} \text{ Btu (-65\%)}.$$

For some applications, however, errors such as these may be acceptable, and the analysis could terminate here.

The second approximation begins by identifying the major single expenses in the budget. Assume that an expert consultant provided a list of such purchases shown in column I of table 4. Care must be taken to identify each expense with its appropriate BEA sector, as defined by the U.S. Department of Commerce (1974).¹⁰

The energy cost calculation for these purchases, including removal of transportation and trade margins and price deflation, is shown in columns II thru VII of table 4. Energy used directly (on-site for construction) should be included in every energy cost calculation, because it may be significant even if it is not a large dollar expense. The energy embodied in the remaining (miscellaneous) inputs to the plant is estimated using the energy/GNP ratio as an average energy intensity as was done in the first approximation.

Column VIII contains the error due to budget uncertainty ($\varepsilon\Delta a$), which is assumed in this example to be 15% for all items. Column IX reflects the uncertainty in the energy intensity ($a\Delta \varepsilon$). The magnitude of the uncertainty in

⁹If the energy/GNP ratio for the appropriate year were not known, construction costs could be deflated to the year for which it is known. A construction cost index is given in table A-2.

¹⁰For convenience, a 90-sector level of aggregation is used in this example. Generally, more accuracy (less aggregation error) can be achieved with the 368-sector level of detail. Tables in the appendix are 368-order, so the numbers in the example will differ slightly from the figures in those tables.

Table 4
Second-approximation energy cost.

^aThe margins removed from all sectors are added to miscellaneous expenses.

^bAll inputs assumed typical except those in 45.00 ($\pm 24\%$).

ε is based on table A-6.¹¹ An examination of table A-6 can indicate whether an input is typical of a particular sector's output. Assume that, based on careful classification and data from the consultant, all inputs except construction machinery (45.00), are believed to be typical sector outputs. Typical inputs can use the figure from table A-6 for their $\Delta\varepsilon$ terms. To account for the atypical construction machinery, an additional 20% is added to the construction machinery uncertainty from table A-6.

The result of calculating the second approximation is a total energy cost of 6.78×10^{12} Btu with error bounds of +53%, -30%.¹² This is an improvement but it still does not fall within our desired $\pm 10\%$ limits.

In the next approximation fewer inputs are classified as miscellaneous in order to further reduce the error. Assume that we instructed the consultant to write down every significant budgeted expense classified in BEA sectors 36.00, 38.00, 40.00, 42.00, 43.00, 45.00, 46.00, 49.00, 53.00, 62.00, and 75.00. These sectors were chosen because they contain most of the materials commonly used for power plant construction; the amounts appear in column I of table 5. As in table 4, computing the energy cost of these purchases is straightforward and the remaining expenses are costed with the average energy/GNP ratio as before. The error analysis proceeds as in the previous step, and this time the error is +15, -13% for an energy cost of 7.19×10^{12} Btu. This still does not meet our accuracy requirements so the analysis must proceed another step.

From table 5 it appears that two of the largest errors are due to budget uncertainties for sectors 43.00 and 40.00. Assume that we have no way of improving the 15% accuracy of the expenses in sector 43.00, but note that the budget figure in sector 40.00 has an unusually large ($\pm 30\%$) error. Assume that, with a small effort, the consultant could improve the error term on structural steel expenses to $\pm 15\%$. This reduces the $\varepsilon\Delta a$ error in that sector and reduces the error bound for the entire power plant to +8, -7%. This is within our error specification and the analysis can now be terminated.

To give an idea of how much effort was saved by these approximations, a complete computation from a line-item budget for the plant is shown in table 6. Column I lists all inputs deflated to 1967 dollars with margins already computed and assigned to the appropriate margin sectors. This is why, for example, sector 65.01 (rail transport) shows an expense of \$883,154 even though the plant budget may not actually show any money allocated to

¹¹These uncertainties apply to the energy intensity of goods in 1967. If we assume the power plant will be built in 1980, the total energy cost will be higher or lower, depending on trends in energy-related technological change throughout the U.S. economy during the 1967-80 period. This correction may be applied after the final result is obtained, and may be approximated by anticipated changes in the aggregate energy/GNP ratio.

¹²Note that for each input, the first-order budget and energy coefficient errors are tabulated. We assume errors on each input item are independent, and therefore the total error in any approximation is the square root of the sum of the squares of each input error.

direct purchases of rail transport. This complete I-O analysis eliminated the large errors due to use of the average energy/GNP ratio as an energy intensity. It can be seen that accuracy has been slightly improved by this method; total energy cost is 7.36×10^{12} Btu $\pm 7\%$.

If a greater degree of accuracy were desired, it would not have been necessary to perform the arduous task of itemizing all inputs, especially the smallest ones. The effort might have been better spent reducing the budget uncertainty on some of the inputs contributing the largest errors. For example, reviewing design details to reduce the budget uncertainty on inputs from sectors 40.00 and 43.00 to $\pm 5\%$ could have improved the estimate in table 5 to $+5\%$, -3% .

If, in this example, there were significant inputs not typical of their sector, similar reductions in the $\Delta\epsilon$ errors may have been achieved by performing a one- or two-step process analysis on several of them.

In closing, we return to the question of the unquantified uncertainty due to the fact that the technologies for producing goods and services changed between 1967 (the model base year) and the time construction of the power plant in 1980. This will have the effect of increasing $\Delta\epsilon$ for all goods and services. Rather than speculating on each production technology individually, it may be easiest to lump the uncertainty in a single factor that attempts to average these effects for all goods and services. The energy/GNP ratio may

be used for this purpose since it is essentially a weighted average of the energy intensities of all production technologies. The ratio has been relatively stable, changing by no more than $\pm 5\%$ for about 20 years, so its impact has been negligible in the past. Anticipating a downward trend in response to post-embargo energy prices, one might wish to adjust the $\Delta\varepsilon$ values accordingly. For our purposes we have neglected this effect; for longer range application, it must be considered explicitly.

3. Discussion

The preceding example outlined the basic steps that must be taken to calculate the energy cost of any item. In the trivial case where the item is a typical output of a sector of the economy, its energy cost can be read directly from table A-6. The example considered an atypical item, an electric power plant, and showed how to perform a one-stage process analysis to obtain a $\pm 10\%$ estimate of its energy intensity.

The foregoing example was structured to highlight the payoffs obtained by focusing attention on a few primary inputs—the most significant element in the first stage of the process analysis. It was seen that it is not always necessary to obtain a detailed breakdown of exact quantities of all input materials in order to obtain a reasonable accurate final result. This technique yields considerable cost savings over conventional analyses that rely on a compilation of accurate and detailed lists of input materials and services.

In the interest of simplicity, the example did not include any two-stage process analyses, because the method is identical to that shown for the first-order step. In practice, the presence of large atypical inputs (e.g., the pressure vessel for a nuclear plant) may result in some of the largest uncertainties being associated with the $\Delta\varepsilon$ terms; it may prove more fruitful to perform crude process analyses on these inputs than to seek more accurate data on input quantities.

The methods developed here can be applied to calculating the energy cost of any good or service within a specified degree of accuracy. This report was written to support energy analyses of energy supply and conservation systems in particular, but applications are not restricted to that area. Detailed guidelines for using this method for net energy analysis are presented by Perry (1977).

Appendix: Tables for computing indirect energy requirements

27.04	C	28911 Glues, Adhesives, and Sizes	12%
		28921 Explosives (except government owned and contractor-operated plants)	7%

*Includes sectors providing more than 1% of the capital costs or more than 5% of the non-energy operating costs for any of the six energy facilities in Just, et al., New Energy Technology Coefficients and Dynamic Energy Models.

**See Code at end of table.

***A major product is one accounting for $\geq 5\%$ of the control total for the sector considered unless noted. See code for explanation of control total.

n.e.c. = not elsewhere classified.

n.s.k. = not specified by kind.

CODE

- A Census of Mineral Industries, reports for SIC sectors comprising BEA sector. Table 5 or 6 depending on aggregation level. Control table is
- B Internal C.A.C. documentation. Control total is gross domestic output.
- C Census of Manufacturers, reports for SIC sectors comprising BEA sector, Table 5B or 6A depending on aggregation. Control total is value of shipments.
- D Census of Business, Vol. 3 Table D: Sales of Merchant Wholesalers, by kind of business.
- E Census of Business, Vol. 1, Table 1: Sales of specified Merchandise Lines. NOTE: Major products here are defined as any line representing $\geq 3\%$ of total sales.
- F Total Insurance Written in 1967 is control total from Best's Insurance Reports - Life/Health 1975 p. vii and "Best's Insurance News," Property-Liability Edition, Vol. 69, No. 6, p. 38. Percentage breakdowns are made directly for property-liability from the latter reference and are based on "sales" for life from "Best's Insurance News," Life Ed., Vol. 68, No. 2, p. 2.
- G Census of Business, Vol. 5, part 1. Table 2: Receipt of All Establishments is control total.
- H Based on 1966 statistics from the Interstate Commerce Commission. Control total is total operating revenue for the entire railroad system (\$11, 163, 422, 895 from Table 109, Transport Statistics 1966.) Major Products listed is a subjective list of identifiable classes of real service from various tables in Transport Statistics, 1966, Part 1.
