Preface

The Agency for Healthcare Research and Quality (AHRQ), through its Evidence-Based Practice Centers (EPCs), sponsors the development of evidence reports and technology assessments to assist public- and private-sector organizations in their efforts to improve the quality of health care in the United States. This report was requested and funded by the National Institutes of Health (NIH), Office of Medical Applications of Research (OMAR). The reports and assessments provide organizations with comprehensive, science-based information on common, costly medical conditions and new health care technologies. The EPCs systematically review the relevant scientific literature on topics assigned to them by AHRQ and conduct additional analyses when appropriate prior to developing their reports and assessments.

To bring the broadest range of experts into the development of evidence reports and health technology assessments, AHRQ encourages the EPCs to form partnerships and enter into collaborations with other medical and research organizations. The EPCs work with these partner organizations to ensure that the evidence reports and technology assessments they produce will become building blocks for health care quality improvement projects throughout the Nation. The reports undergo peer review prior to their release.

AHRQ expects that the EPC evidence reports and technology assessments will inform individual health plans, providers, and purchasers as well as the health care system as a whole by providing important information to help improve health care quality.

We welcome comments on this evidence report. They may be sent by mail to the Task Order Officer named below at: Agency for Healthcare Research and Quality, 540 Gaither Road, Rockville, MD 20850, or by e-mail to epc@ahrq.gov.

Structured Abstract

Objectives. To systematically review the evidence on the use of inhaled nitric oxide (iNO) in preterm infants born at or before 34 weeks gestation age who receive respiratory support.

Data sources. We searched MEDLINE, EMBASE, the Cochrane Central Register of Controlled Studies (CENTRAL) and PsycInfo in June 2010. We also searched the proceedings of the 2009 and 2010 Pediatric Academic Societies Meeting and ClinicalTrials.gov. We identified additional studies from reference lists of eligible articles and relevant reviews, as well as from technical experts.

Review methods. Questions were developed in collaboration with technical experts, including the chair of the upcoming National Institutes of Health Office of Medical Applications of Research Consensus Development Conference. We limited our review to randomized controlled trials (RCTs) for the question of survival or occurrence of bronchopulmonary dysplasia (BPD) and for the question on short-term risks. All study designs were considered for long-term pulmonary or neurodevelopmental outcomes, and for questions about whether outcomes varied by subpopulation or by intervention characteristics. Two investigators independently screened search results, and abstracted data from eligible articles.

Results. We identified a total of 14 RCTs, reported in 23 articles, and eight observational studies. Mortality rates in the NICU did not differ for infants treated with iNO versus those not treated with iNO (RR 0.97 (95% CI 0.82, 1.15)). BPD at 36 weeks for iNO and control groups also did not differ (RR 0.93 (0.86, 1.003) for survivors). A small difference was found between iNO and control infants in the composite outcome of death or BPD (RR 0.93 (0.87, 0.99)). There was inconsistent evidence about the risk of brain injury from individual RCTs, but meta-analyses showed no difference between iNO and control groups. We found no evidence of differences in other short term risks. There was no evidence to suggest a difference in the incidence of cerebral palsy (RR 1.36 (0.88, 2.10)), neurodevelopmental impairment (RR 0.91 (0.77, 1.12)), or cognitive impairment (RR 0.72 (0.35, 1.45)). Evidence was limited on whether the effect of iNO varies by subpopulation or by characteristics of the therapy (timing, dose and duration, mode of delivery, or concurrent therapies).

Conclusions. There was a seven percent reduction in the risk of the composite outcome of death or BPD at 36 weeks PMA for infants treated with iNO compared to controls, but no reduction in death or BPD alone. Further studies are needed to explore particular subgroups of infants and to assess long term outcomes including function in childhood. There is currently no evidence to support the use of iNO in preterm infants with respiratory failure outside the context of rigorously conducted randomized clinical trials.

Executive Summary

Background

Neonatal lung disease is the most common complication of preterm delivery and causes significant morbidity and mortality. Disorders of prematurity and respiratory distress are among the leading causes of infant mortality in the U.S.

The use of inhaled nitric oxide (iNO) has been approved by the U.S. Food and Drug Administration for respiratory failure of the term and near-term infant and is recommended by professional societies, such as the American Academy of Pediatrics. Evidence supporting the use of iNO in term or near term infants is summarized by a Cochrane review that found that use of iNO therapy reduced the need for extracorporeal membrane oxygenation in term and near term (> 34 weeks gestation) infants with respiratory failure, but did not change neurodevelopmental outcomes at two to three years of age. There is a need to consider the evidence about the use of iNO therapy in preterm infants \leq 34 weeks of gestation.

This report summarizes the available evidence on the use of iNO in preterm infants born at or before 34 weeks gestation age who receive respiratory support. The report addresses the following questions:

1. Does iNO therapy increase survival and/or reduce the occurrence or severity of bronchopulmonary dysplasia (BPD) among premature infants who receive respiratory support?
2. Are there short-term risks of iNO therapy among premature infants who receive respiratory support?
3. Are there effects of iNO therapy on long-term pulmonary and/or neurodevelopmental outcomes among premature infants who receive respiratory support?
4. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary across subpopulations of premature infants?
5. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary by timing of initiation, mode of delivery, dose and duration, or concurrent therapies?

Methods

We searched MEDLINE, EMBASE, the Cochrane Central Register of Controlled Studies (CENTRAL) and PsycInfo in June 2010. We also searched the proceedings of the 2009 and 2010 Pediatric Academic Societies Meeting and ClinicalTrials.gov. We identified additional studies from reference lists of eligible articles and relevant reviews, as well as from technical experts. Questions were developed in collaboration with technical experts, including the chair of the upcoming National Institutes of Health Office of Medical Applications of Research Consensus Development Conference. We limited our review to randomized controlled trials (RCTs) for the question of survival or occurrence of bronchopulmonary dysplasia (BPD) and for the question on short-term risks. All study designs were considered for long-term pulmonary or neurodevelopmental outcomes, and for questions about whether outcomes varied by subpopulation or by intervention characteristics. Two investigators independently screened search results, and abstracted data from eligible articles.

Results

We identified a total of 14 RCTs, reported in 23 articles, and eight cohort studies addressing our questions. Our major findings are summarized by key question.

Key Question 1. Does iNO therapy increase survival and/or reduce the occurrence or severity of bronchopulmonary dysplasia (BPD) among premature infants who receive respiratory support?

- There is no statistically significant effect of iNO compared to placebo on survival or mortality rates in preterm NICU infants requiring mechanical ventilation.
- There is insufficient evidence to determine whether iNO reduces the rate of bronchopulmonary dysplasia (BPD), as defined by requiring supplemental oxygen at 36 weeks postmenstrual age, in preterm NICU infants requiring mechanical ventilation.
- There is small but statistically significant reduction in the composite variable of death or BPD at 36 weeks PMA for infants treatment with iNO compared to infants in control groups.
- Preterm infants who required mechanical ventilation and were the subjects of randomized controlled trials of inhaled nitric oxide were a high risk population with high mortality and BPD rates during NICU hospitalization.

Fourteen RCTs addressed death or BPD. The definition of outcomes, specifically the time outcomes were assessed, differed across studies. Evidence on the outcome of death was considered of moderate strength as was BPD at 36 weeks PMA.

Key Question 2. Are there short-term risks of iNO therapy among premature infants who receive respiratory support?

- There is insufficient evidence of a neuroprotective effect of iNO in preterm infants.
- There is no evidence that treatment of preterm infants with iNO influences the rates of other complications of prematurity, including patent ductus arteriosus (PDA), sepsis,

- necrotizing enterocolitis (NEC), severe retinopathy of prematurity (ROP), pulmonary hemorrhage, or air leaks.
- No study reported accumulation of toxic levels of methemoglobin or nitrogen dioxide.

Fourteen RCTs provided data on short term risks of iNO therapy. There was moderate strength of evidence on IVH, PVL, PVL, PDA and NEC.

Key Question 3. Are there effects of iNO therapy on long-term pulmonary and/or neurodevelopmental outcomes among premature infants who receive respiratory support?

- There is insufficient evidence to determine whether iNO therapy in preterm infants who require respiratory support influences the incidence of cognitive, motor or sensory impairments, or neurodevelopmental disability.
- There is evidence suggesting that iNO therapy in preterm infants who require respiratory support may decrease the need for respiratory medications at one year of age.
- There is insufficient evidence to determine whether iNO therapy in preterm infants who require respiratory support impacts long-term health outcomes such as respiratory symptoms, rehospitalization after NICU discharge, and growth.

Twelve articles reported long term outcomes; nine RCTs and three observational studies. Evidence was considered to be of low strength for neurodevelopmental and cognitive outcomes and for cerebral palsy. Evidence for death as a long term outcome was moderate. Evidence on all of the other long term outcomes was considered low or insufficient.

Key Question 4. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary across subpopulations of premature infants?

- There is insufficient evidence to determine whether the effect of iNO therapy on mortality, BPD, or motor impairment differs by the birth weight of the treated infants.
- There is insufficient evidence to evaluate the relationship between iNO therapy and infant sex, race/ethnic group, gestational age, or socioeconomic status.
- There are no published data available to evaluate the association between iNO therapy and, antenatal steroids, chorioamnionitis, multiple birth, or growth restriction.
- There is insufficient evidence concerning the relationship between iNO therapy and the severity of illness.
- There is insufficient evidence that iNO therapy improves outcome of infants suffering respiratory failure from pulmonary hypoplasia, respiratory distress syndrome or pulmonary hypertension.
- There is no consistent pattern of infants that respond to iNO therapy and those that do not.
- There is no consistent pattern of infants that respond to iNO therapy and those that do not.

We identified six RCTs with five followup studies, and six other studies, that addressed this question. The definition of outcomes varied across studies, and many of the subgroup analyses were by post hoc analyses. Death, BPD at 36 weeks PMA and survival without BPD had

moderate strength of evidence. All other outcomes for this question had evidence judged to be low strength.

Key Question 5. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary by timing of initiation, mode of delivery, dose and duration, or concurrent therapies?

- There is insufficient evidence to determine if initiating iNO therapy for acute respiratory distress at ≤ 3 days reduces the risk of death or bronchopulmonary dysplasia (BPD) at 36 weeks PMA, or death and neurodevelopmental disability at 1 year of age, corrected for gestational age at birth.
- In infants with developing BPD, there is insufficient evidence to determine if treatment with iNO during the second week after birth improves survival without BPD compared with treatment during the third week after birth.
- There is insufficient evidence to determine the effect of delivery of iNO by high frequency ventilation on either death or BPD, or neurodevelopmental outcome compared with conventional ventilation.
- There is insufficient evidence to support an optimal dose of iNO or duration of exposure to improve outcome or prevent harm.
- There is insufficient evidence to determine the effect of iNO with concurrent therapy.

We identified 14 RCTs addressing this question. No studies allowed for assessment of duration of therapy. Comparison across studies was limited by differences in definitions of outcomes. All but two of the studies provided data based on post hoc analysis, and so should be interpreted with caution. Strength of evidence was moderate for survival without BPD and BPD at 36 weeks. For all other outcomes, evidence was low strength.

Future Research

Current evidence does not support the routine use of iNO to treat premature infants. However, we should not abandon the possibility that iNO may someday become a component of a treatment strategy for some preterm infants receiving respiratory support. Several factors contribute to our recommendation to continue the study of iNO: 1) our finding a small but statistically significant difference in death or BPD at 36 weeks PMA, the common primary outcome variable of 73% of RCT conducted to-date; 2) the statistically significant finding of a diminished need for chronic pulmonary medication at one year corrected age, suggesting less severe lung disease in those treated with iNO, and 3) no studies have been powered to detect meaningful differences in infant functional outcome or quality of life with iNO treatment compared to standard therapy.

Specific considerations for future research are listed below.

Patients

- RCTs must be adequately powered to assess the effect of iNO on subgroups of preterm infants, such as those of varying birth weight.

- Special care must be taken if infants born at the limit of viability are included in RCTs. These infants do not yet have alveoli (gas exchange occurs through their terminal bronchioles) and their brains do not yet have gyri or sulci. They are most vulnerable to organ injury, which may be most evident on long-term follow-up. Every effort must be taken to obtain pulmonary, neurodevelopmental and health follow-up for all infants in this category.
- There may be a value to viewing the use of iNO in terms of postmenstrual age, which is a better measure of degree of maturation and takes into account both gestational age and chronologic age in developing preterm infants.

Intervention

- Since the goal is to support pulmonary and brain development in the NICU, courses of iNO given for weeks, not days, should be studied.
- Mode of ventilation should be considered in randomization schemes for trials restricted to infants < 1500 grams, those at highest risk for death, BPD and neurodevelopmental impairment, to adequately address the question concerning mode of delivery.
- As many of the smallest preterm infants are managed with CPAP or high flow nasal cannula alone, without intubation, information concerning iNO delivery with these devices is needed.

Outcomes

- Future RCTs should require neuroimaging by standardized protocols before trial enrollment, to detect the occurrence and progression of brain injury during iNO treatment.
- Studies should be powered to assess long term neurodevelopmental, pulmonary and other health outcomes.
- Outcomes should focus on functional status and quality of life, as well as neurodevelopmental disabilities.
- Studies are needed to provide information on resource utilization such as rehospitalizations, medications, physicians' visits. Future focus should be on the real pulmonary problems of prolonged hospitalizations, use of supplemental oxygen and pulmonary medications after NICU discharge, prevalence of reactive airway disease and recurrent hospitalizations.
- Consideration should be given to assess longer term childhood outcomes (e.g., pulmonary function tests, school performances).
- Cost benefit analyses should be conducted with multicenter RCTs of iNO.

Evidence Report

Chapter 1. Introduction

Background

Neonatal lung disease is the most common complication of preterm delivery, and results in significant morbidity and mortality.¹ Preterm infants suffer from both acute and chronic respiratory failure as a result of anatomic and biochemical disruption of lung function, lung inflammation and oxidative stress, nutritional deficiencies, and arrest of tracheobronchial and pulmonary vascular growth (see Appendix A^a, List of Acronyms). Treatment for acute respiratory failure often contributes to evolving bronchopulmonary dysplasia (BPD) and chronic respiratory failure, due to barotrauma and oxygen toxicity from prolonged respiratory support, deficient nutrition, as well as immaturity of lung growth, vascular development and immunologic defenses. Pulmonary hypertension may occur in association with acute and/or chronic respiratory failure.² Multiple etiologies make finding an effective treatment for respiratory failure in preterm infants challenging. Disorders related to prematurity and respiratory distress are among the leading causes of infant mortality in the U.S.³

Treatment Options

Treatment options for respiratory failure in preterm infants include a variety of modalities. Prenatal steroids, antibiotics, exogenous surfactant replacement, tidal volume ventilation, conventional ventilation, continuous positive airway pressure, high flow oxygen administration, and high frequency ventilation are all used as therapeutic modalities. Treatment of preterm infants with inhaled nitric oxide (iNO) as a rescue therapy for refractory hypoxemic respiratory failure is an extension of the relative success of the treatment of term and near term infants with iNO.⁴

Mechanism of Action

Endogenous nitric oxide (NO), produced in vascular endothelial cells, regulates vascular tone.⁵ NO diffuses into adjacent vascular smooth muscle cells and activates soluble guanylyl cyclase, leading to the activation of cGMP-dependent protein kinase.⁶ The subsequent signal transduction cascade results in vascular smooth muscle cell relaxation and vasodilatation.^{6,7} When exogenous nitric oxide is inhaled, it is a selective pulmonary vasodilator decreasing pulmonary vascular resistance without affecting systemic vascular tone.⁸ This occurs because the low molecular weight and high lipid solubility of inhaled NO allows rapid diffusion in the ventilated lung from the alveoli to direct contact with arterioles.⁹ In addition, NO has a very short half-life,^{5,10} and NO is rapidly deactivated by heme in hemoglobin reducing its effect on other smooth muscle in the body.^{11,12}

Since 1999, iNO has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of severe hypoxemia and persistent pulmonary hypertension of the newborn

^a Appendixes and evidence tables for this report can be found at:
<http://www.ahrq.gov/downloads/pub/evidence/pdf/inoinfants/inoinfants.pdf>

(PPHN) in term and near term infants.¹³ PPHN is a syndrome associated with several neonatal cardio pulmonary etiologies, and is characterized by high pulmonary vascular resistance (PVR).⁷ High PVR causes extrapulmonary shunting of blood right to left across the ductus arteriosus and/or foramen ovale and may cause critical hypoxemia.^{7, 14} In newborns, the use of iNO therapy to selectively lower PVR and reduce extrapulmonary shunting accounts for the acute improvement in oxygenation observed with PPHN.¹⁵

In severe respiratory failure, hypoxemia may also occur with intrapulmonary shunting, due to atelectasis and ventilation/perfusion inequality.⁷ Thus, inhaled nitric oxide may also benefit preterm infants with parenchymal lung disease by redistributing pulmonary blood flow, thereby reducing intrapulmonary shunting and ventilation: perfusion mismatching.¹⁶ Both mechanisms reduce secondary lung injury from barotrauma, volutrauma, and oxygen toxicity by reducing the need for prolonged respiratory support.

Inhaled NO may have other characteristics beneficial to preterm infants. Ballard, 2006 demonstrated that iNO therapy in a preterm baboon model of evolving BPD increased maximal lung volume, decreased the total protein:phospholipid (PL) ratio of surfactant, and had little effect on the composition of surfactant PL or proteins, suggesting that iNO may be associated with less severe lung injury and improved surfactant function.¹⁷ In a companion study, again in a premature baboon model, McCurnin, 2005 reported lung growth after iNO therapy mimicked that seen in utero.¹⁸ Inhaled NO has also been shown to reduce inflammation and oxidant injury in animal models of hyperoxic lung injury.^{19, 20} Furthermore, NO may play a role in early lung development. A newborn rat model with both structural and functional characteristics of BPD²¹ showed a reduction in pulmonary hypertension and a preservation of lung growth with early introduction of iNO therapy.²¹ Similarly, following exposure to hyperoxia in neonatal rats, Lin, 2005 found that iNO exposure during recovery restored distal lung growth and alveolarization.²²

Inhaled NO has several potential toxic complications from both direct and indirect effects.²³ The preterm infant is particularly vulnerable to reactive oxidant species induced damage due to the relative inadequacy of antioxidant enzymes in the lung.²⁴ In the presence of oxygen, nitric oxide forms nitrogen dioxide (NO₂), a potent inflammatory agent leading to pulmonary edema and lung injury, but the formation is slow at low levels of NO₂.^{11, 25} A NO₂ dose of 5 ppm is considered the maximum environmentally safe dose, necessitating careful monitoring of infants receiving iNO therapy.²⁶ In simulation, delivery of 20 ppm iNO at high oxygen concentrations resulted in the formation of < 1 ppm NO₂. NO may also adversely affect platelet aggregation and adhesion,²⁷ although the evidence is conflicting²⁸ and has not been reported in trials with infants.

Methemoglobinemia, the resultant reaction of nitric oxide with hemoglobin, reduces oxygen carrying capacity at high concentrations. Accumulation of toxic levels of methemoglobin have not been demonstrated when iNO is delivered at < 80ppm,²⁹ the range in which most infants are treated, but requires constant monitoring during treatment.

FDA Approved Indication and Usage

The U.S. FDA approved iNO for use in intubated full term and late preterm infants with hypoxemic respiratory failure in 1999¹³ Current labeling of iNO is for use in respiratory failure in term and near term infants (> 34 weeks gestation). The initial recommended starting dose for these infants is 20 ppm with continued use for 14 days or until improvement in the underlying disease process results in normal oxygen saturations. The dose is weaned incrementally with improving oxygen saturations beginning as soon as four hours after the initiation of therapy, to 5

ppm before discontinuation. For infants that do not respond to initial iNO therapy, the dose may be increased to 40 to 80 ppm. Brief exposure to these higher doses appears to be safe, but sustained treatment with 80 ppm will increase the risk of methemoglobinemia,⁷ with little added clinical benefit.

Utilization of iNO

Since the FDA approval for use of iNO in full term and late preterm infants, a number of studies have been conducted on the use of iNO in clinically diverse populations of preterm infants.³⁰⁻⁴⁰ These studies demonstrate significant variability in their clinical indications for the use of iNO, from its prophylactic use in preterm infants with mild acute respiratory distress to prevent BPD and chronic lung disease, to its use as a late rescue therapy for preterm infants with severe BPD, with resulting wide variations in inclusion and exclusion criteria for study samples. There has been considerable variation in dosage and timing of iNO among studies. Differing findings regarding pulmonary effects and effects on the most common primary outcome variable, death or BPD, raises concerns about gaps in our understanding of physiological effects of iNO in the rapidly developing preterm lung. In addition, differences in the direction of effect on the developing preterm brain raise questions as to whether treatment of preterm infants with iNO increases or decreases the incidence of brain injury.

This controversy has resulted in wide variations in clinical practice, as reports of the longer term pulmonary and neurodevelopmental outcomes at ages two to six years are just emerging.

Purpose of This Evidence Report

Inhaled NO has demonstrated efficacy in improving oxygenation and reducing the need for extracorporeal membrane oxygenation (ECMO) in late preterm infants born after 34 weeks gestation and full term infants with respiratory failure, with no evidence of long term benefits.⁴ Despite the approved use of iNO in full term and late preterm infants, the developmentally distinct mechanisms of respiratory failure and differing cardiovascular, pulmonary, and pharmacokinetic characteristics of more immature infants require systematic study of the short and long term outcomes for preterm infants treated with iNO to prevent or treat respiratory failure.

A 2006 meta-analysis included five randomized controlled trials (RCTs) with 808 infants born before 34 weeks gestation.³² The authors concluded that while preterm infants treated with iNO had reduced treatment failure (death or chronic lung disease (CLD); RR 0.81 (0.70, 0.93)) further research was needed on risks and on later neurodevelopmental outcomes. A 2007 Cochrane review of 11 RCTs analyzed data on 3,251 preterm infants (defined as < 35 weeks gestation) in terms of illness severity, dose and timing of iNO.³¹ The Cochrane review concluded that iNO has no proven efficacy as a rescue therapy to treat very ill ventilated preterm infants, and it may increase the incidence of brain injury (one trial was stopped early).³¹ It did not appear to prevent chronic lung disease or BPD in preterm infants. Subgroup analyses in some of the multicenter RCTs of iNO in preterm infants suggest that iNO may be beneficial in some preterm infants (e.g., those with higher birth weights, milder respiratory illness, or persistent pulmonary hypertension).^{32, 40-42}

The Cochrane review acknowledged very limited data on long term outcomes of preterm infants treated with iNO. If iNO is beneficial, the number need to treat would be very large.

Papers published or presented from 2007 to present report conflicting results as to whether, in preterm infants, iNO has beneficial, adverse, or no effects on long term neurodevelopmental and pulmonary outcomes.^{30, 43-46}

Despite the ongoing controversy, iNO continues to be used for hypoxemic respiratory failure in preterm infants < 34 weeks gestation even with potential harm to the developing lungs and brain.⁴⁷ There is an urgent need to weigh the current evidence as to whether iNO is a safe and effective treatment in preterm infants.

The Office of Medical Applications of Research (OMAR) at the National Institutes of Health (NIH) scheduled an NIH Consensus Development Conference: Inhaled Nitric Oxide in Preterm Infants to be held in October 2010. The Evidence-based Practice Center at the Johns Hopkins University (JHU) was asked by OMAR and the Agency for Healthcare Research and Quality (AHRQ) to prepare an evidence report for this conference.

Key Questions

We sought to identify and synthesize evidence addressing the following questions:

1. Does inhaled nitric oxide (iNO) therapy increase survival and/or reduce the occurrence or severity of bronchopulmonary dysplasia (BPD) among premature infants who receive respiratory support?
2. Are there short term risks of iNO therapy among premature infants who receive respiratory support?
3. Are there effects of iNO therapy on long term pulmonary and/or neurodevelopmental outcomes among premature infants who receive respiratory support?
4. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary across subpopulations of premature infants?
5. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary by timing of initiation, mode of delivery, dose and duration, or concurrent therapies?

For the purposes of our review, we sought studies that included infants less than or equal to 34 weeks gestation age. The outcomes of interest are described in detail in Chapter 2.

Chapter 2. Methods

Our objective was to review and synthesize the evidence on the use of inhaled nitric oxide (iNO) in preterm infants born at or before 34 weeks gestation age who require respiratory support. This review addresses the short term outcomes bronchopulmonary dysplasia, cardiopulmonary risks, infectious risks, neurological risks, as well as short term survival and death. Long term outcomes including pulmonary outcomes, neurodevelopmental outcomes, growth, chronic medical conditions, and survival to childhood were also assessed. The results of this report will be presented to an NIH Consensus Panel in October 2010.

Topic Development

The core team worked with technical experts, the NIH Consensus Panel Chair, to develop and refine the Key Questions that are presented in Chapter 1 (Introduction). Prior to searching for literature, we clarified the definitions of these key questions and the types of evidence which we would include in our review. Topic development was facilitated by the results of preliminary searches, discussions among team members, and input from our Technical Expert Panel.

Key Questions 1 and 2 address short term impact of iNO use on preterm infants. Key Question 1 addresses the impact of iNO on survival and/or bronchopulmonary dysplasia. Key Question 2 addresses short term risks to preterm infants receiving iNO therapy. Based on discussion with our experts, we decided to limit our review to randomized controlled trials for these two questions.

Key Question 3 addresses long term outcomes of iNO use in preterm infants. This question focuses on pulmonary and neurodevelopmental outcomes. We did not limit the consideration of studies by study design. We identified, and abstracted separately case reports and case series. However, we ultimately chose not to include case reports and case series in our formal review as the level of detail in these reports was generally insufficient.

The impact of iNO therapy on bronchopulmonary dysplasia, death, and/or neurodevelopmental outcomes across subpopulations of premature infants is addressed in Key Question 4, and influence of the timing of initiation, mode of delivery, dose and duration, or concurrent therapies is addressed in Key Question 5. Included studies for this question were not limited by study design except for the exclusion of case reports and case series, as for Key Question 3.

Analytic Framework

We developed a framework (Figure 1) to illustrate the components of the key questions, including the population, intervention and outcomes. The framework also delineates the subgroups; treatment characteristics, such as dose of iNO; and specific short and long term outcomes of interest. Short term outcomes were defined as adverse events and clinical outcomes associated with iNO treatment that occur during the initial hospitalization after birth. Long term outcomes were defined as the effects of iNO treatment on infant health and functional outcome in early childhood and include measures of chronic pulmonary disease, growth, developmental delay and disability, and survival.

Search Strategy

Searching the literature involved identifying reference sources, formulating a search strategy for each source, and executing and documenting each search. For the searching of electronic databases we used controlled vocabulary terms (i.e., MeSH, Emtree), combined with text words for iNO (see Appendix B^b, Detailed Search Strategies) We also looked for eligible studies by reviewing the references in pertinent reviews, by scanning conference proceedings, by querying our experts, and through knowledge shared at core team meetings.

Sources

Our search included electronic and hand searching. On November 9, 2009, we ran searches of MEDLINE[®] (using PubMed), EMBASE[®], the Cochrane Central Register of Controlled Studies (CENTRAL), and PsycInfo databases. These searches were run again on June 23, 2010. We also searched the references of articles included in this study and those tagged as of interest during the screening process. As information on long term outcomes for infants treated with iNO is just emerging, we also scanned the proceedings of the Pediatric Academic Societies Meetings in 2009 and 2010. ClinicalTrials.gov was searched for ongoing or completed trials. Investigators of ongoing trials were not contacted for information. We decided that the investigators conducting ongoing trials would only be contacted if they were studying outcomes with no published information. There were no limits used in the searches, including any based on publication date.

Search Terms and Strategies

We developed a strategy for MEDLINE, accessed via PubMed, based on an analysis of the MeSH terms and text words of key articles identified *a priori*. The PubMed strategy formed the basis for the strategies developed for the other electronic databases (see Appendix B).

Organization and Tracking of the Literature Search

The results of the searches were downloaded into ProCite[®] version 5.0.3 (ISI ResearchSoft, Carlsbad, CA). Duplicate articles retrieved from the multiple databases were removed prior to initiating the review. From ProCite, the articles were uploaded to Distiller SR[®] (Evidence Partners, Ottawa, Ontario). We used this software to store full articles in portable document format (PDF) and to track the results of the abstract screen, article screen, and data abstraction.

^b Appendixes and evidence tables for this report can be found at:
<http://www.ahrq.gov/downloads/pub/evidence/pdf/inoinfants/inoinfants.pdf>

Study Selection

Abstract Screen

Each abstract was independently screened by two reviewers. An abstract was excluded at this level if it did not report any original data, did not include human data, did not include infants born at less than or equal to 34 weeks of gestation, did not include preterm infants requiring respiratory support, did not include preterm infants treated with inhaled nitric oxide, did not address any of the key questions, or addressed Key Question 1 and or 2 but was not a randomized controlled trial. An option was provided for reviewers to indicate other reasons for exclusion. Articles tagged as non English were reviewed by individuals fluent in the language of publication to determine eligibility. (Appendix C, Abstract Review Form).

Abstracts were promoted to be screened using full text article if both reviewers agreed that the abstract could apply to one or more of the key questions. An abstract could be excluded for different reasons by the two reviewers. Disagreements about the eligibility of an abstract were resolved by discussion between the two reviewers or by adjudication of a third reviewer.

Article Screen

Full text articles underwent another independent review by paired investigators to determine whether they should be included in the full data abstraction (see Appendix C, Article Inclusion/Exclusion Form). If articles were deemed to have applicable information, they were included in the data abstraction. Articles could be excluded at this level for the same set of reasons used at the abstract screen level with an additional exclusion criterion of no abstractable data. Articles that had English language abstracts that were promoted to this level but were tagged for exclusion as “not English language” were reviewed by investigators fluent in the specific language for eligibility.

Articles were promoted to data abstraction if both reviewers agreed. An article could be excluded for different reasons by the two reviewers. Disagreements about the eligibility of an article were resolved by discussion between the two reviewers or by adjudication of a third reviewer.

Data Abstraction

We used an independent review process to abstract data from the included articles. In this process, both a clinical expert and a research assistant completed all relevant data abstraction forms independently. Reviewers were not masked to the articles’ authors, institutions, or journal.⁴⁸ Disagreements that could not be resolved between the reviewers were resolved through consensus adjudication at team meetings.

For all articles, reviewers extracted information on general study characteristics: study design, whether the study was a followup or additional analysis of another study, location, recruitment start and end dates, inclusion and exclusion criteria, description of the study intervention, iNO dose and duration, and length of followup (see Appendix C, Study

Characteristics Form). Participant characteristics were also abstracted: number of participants, gestational age, birth weight, participant age, sex, and relevant background data such as disease severity, mode of ventilation, and concurrent medications. Maternal characteristics were also collected on this form (see Appendix C, Participant Characteristics Form).

Reviewers abstracted data, for all study arms and subgroups, on a predefined set of outcomes (see Appendix C, All Outcomes). Case reports were abstracted separately to identify whether they included data relevant to this study (see Appendix C, Case report form). These data were ultimately not included as the level of detail in these reports was generally insufficient.

Quality Assessment of Individual Studies (Risk of Bias Assessment)

In order to assess the risk of bias in randomized controlled trials, we used the Cochrane Collaboration Tool for Assessing Risk of Bias from the Cochrane Handbook for Systematic Reviews of Interventions.⁴⁹ This tool was used to assess six categories of potential bias; (1) sequence generation, (2) allocation concealment, (3) blinding, (4) incomplete data reported, (5) selective reporting bias as well as (6) other sources of bias. For each bias category reviewers answered one or more questions and entered “Yes” for a low risk of bias, “No” for a high risk of bias or “Unclear.”

For the observational studies we adapted the Newcastle-Ottawa Scale in order to determine the risk of bias of the reported data in both cohort and case control studies.⁵⁰ This form assessed possible sources of bias including (1) representativeness of the study cohort, (2) selection of the control cohort (if applicable), (3) selection of treated patients, (4) presence of the outcome of interest at the start of the study, (5) comparability of the cohorts, (6) reporting bias, (7) whether the followup was long enough for outcomes to occur, and (8) incomplete data reported. Similar to the risk of bias forms for randomized control trials, we used question based forms where reviewers entered “Yes” for a low risk of bias, “No” for a high risk of bias or “Unclear” for questions about each source of bias.

The risk of bias forms were completed independently by paired reviewers. In the case of a disagreement, the two original reviewers conferred and agreed upon a single answer. These assessment instruments are included in Appendix C, Risk of Bias Forms.

Grading of the Body of Evidence

At the completion of our review, we assessed the quantity, quality and consistency of the body of available evidence addressing Key Questions 1 through 5. We used an evidence grading scheme recommended by the GRADE Working Group, and adapted by AHRQ in their Draft Methods Guide,⁵¹ and recently published in the Journal of Clinical Epidemiology.⁵² We considered the strength of the study designs with randomized controlled trials as the highest level of evidence, followed by observational studies. If an outcome was evaluated by at least one randomized controlled trial as well as observational studies our evidence grade was based on the randomized controlled trials and followed by the quality of the cohort studies. If an outcome was

evaluated by one or no randomized controlled trials, our evidence grade was based on the single randomized controlled trial in addition to the best available observational study.

We assessed the quality and consistency of the best available evidence, including assessment of the risk of bias in relevant studies, as well as aspects of consistency, directness, and precision as described in the Draft Methods Guide⁵¹ and Owens, 2010.⁵²

For each outcome of interest, two investigators graded the major outcomes for each Key Question and then the entire team discussed their recommendations and reached consensus.

Data Synthesis

We created a set of detailed evidence tables containing information extracted from eligible studies. We stratified the tables according to applicable key question. Once evidence tables were created, we rechecked selected data elements against the original articles. If there was a discrepancy between the data abstracted and the data appearing in the article, this discrepancy was brought to the attention of the investigator in charge of the specific data set and the data were corrected in the final evidence tables.

Meta-analyses were completed using MetaAnalyst. The program was developed by the Tufts Evidence-based Practice Center under contract with AHRQ.⁵³ The analyses were performed using a Der-Simonian Laird random effects model.⁵⁴ In this program, a Woolf-Haldane continuity correction of 0.5 was used when a cell contained zero events.⁵⁵ In all analyses, we examined the risk ratio for each outcome. Sensitivity analyses were performed to determine stability of the results. In general, meta-analyses were completed for outcomes reported across more than one study where the definition and measurement of the outcome was determined to be similar. Where relevant, further details regarding the decision to conduct or not conduct meta-analyses, the inclusion and exclusion of articles from the meta-analysis, and any sensitivity analyses, are provided in the results section.

Peer Review

We recruited external technical experts from diverse professional backgrounds, including neonatology, pulmonology, cardiology, and neurodevelopment. The technical experts were asked for input regarding key steps of the process, including development of the analytic framework, outcomes, and search strategies. In addition to the technical experts, three peer reviewers were recruited from various clinical and methodological settings.

Throughout the project, the core team sought feedback from the external technical experts and the NIH Panel Chair. A draft of the report was sent to the technical experts and peer reviewers, as well as to representatives of AHRQ, and the NIH Office of Medical Applications Research Panel Chair for this project. In response to the comments from the technical experts and peer reviewers, we revised the evidence report and submitted a summary of the comments and their disposition.

Chapter 3. Results

Literature Search/Abstract/Article Review

The literature search process identified 3104 unique citations. During the abstract review process, we excluded 2650 citations that did not meet one or more of the eligibility criteria (see Chapter 2 for details). At article review, we excluded an additional 423 articles that did not meet one or more of the eligibility criteria (see Appendix D^c, Excluded Articles). Thirty-one articles were eligible for inclusion in the review. There were 14 RCTs described in 23 articles, and eight observational studies (Figure 2).

Description of the Types of Studies Retrieved

There were 14 articles that applied to Key Question 1. Fourteen articles (all RCTs) applied to Key Question 2. Twelve articles applied to Key Question 3; three original RCTs with six followup studies, and three observational studies. Seventeen articles applied to Key Question 4; six RCTs with four followup studies, and seven cohort studies. Twenty-one articles applied to Key Question 5; 14 RCTs with seven followup studies (Table 1). Eight studies containing 13 case reports were also examined. As mentioned in Chapter 2, we reviewed the case reports and determined that the data were not of sufficient detail to be considered further.

Risk of Bias

As described in Chapter 2, we assessed each individual study for risk of bias using a study design specific tool. (See Appendix E, Evidence Tables 1 and 2.)

The RCTs and their followup studies were not assessed separately for risk of bias. Six of the 14 RCTs (along with their five followup studies) were assessed as having low risk of bias.^{30, 34, 36, 37, 39, 40, 44, 56, 57, 58, 59} Three of the RCTs were determined to be at fair risk of bias.⁶⁰⁻⁶² The remaining five RCTs were assessed as having a high risk of bias.⁶³⁻⁶⁷ Figure 3 provides a summary of the risk of bias for the RCTs. (Appendix E, Evidence Table 1).

None of the eight observational studies were considered to have a low risk of bias. Five received a fair risk of bias assessment, and received this score for a variety of reasons.^{38, 68-71} Three observational studies were assessed at high risk of bias.⁷²⁻⁷⁴ (Appendix E, Evidence Table 2).

Key Question 1: Does inhaled nitric oxide (iNO) therapy increase survival and/or reduce the occurrence or severity of bronchopulmonary dysplasia (BPD) among premature infants who receive respiratory support?

Major Findings

- There is no statistically significant effect of iNO compared to placebo on survival or mortality rates in preterm NICU infants requiring mechanical ventilation.
- There is insufficient evidence to determine whether iNO reduces the rate of bronchopulmonary dysplasia (BPD), as defined by requiring supplemental oxygen at 36 weeks postmenstrual age, in preterm NICU infants requiring mechanical ventilation.
- There is a small but statistically significant reduction in the composite variable of death or BPD at 36 weeks PMA for infants treated with iNO compared to infants in control groups.
- Preterm infants who required mechanical ventilation and were the subjects of randomized controlled trials of inhaled nitric oxide were a high risk population with high mortality and BPD rates during NICU hospitalization.

Detailed Analysis

We identified 14 RCTs that compared treatment with iNO to standard treatment in preterm infants requiring mechanical ventilation (Table 2). They varied as to inclusion and exclusion criteria; age of enrollment; dose, timing and duration of iNO; and outcome variables reported. Current labeling of iNO is for use in infants born after 34 weeks gestation with respiratory failure, so we included two RCTs of preterm infants born *at or before* 34 weeks gestation.^{59, 79} All but one RCT began enrollment and started iNO during the first week after birth; the RCT that differed from the others enrolled infants and started iNO at seven to 21 days after birth.³⁴ The 14 RCTs varied widely as to severity of respiratory illness, birth weight (BW), gestational age, chronological age from birth, and postmenstrual age (PMA, gestational age plus chronological age, a proxy for degree of prematurity) when treatment was initiated (Table 3). Their study designs varied widely in terms of dose (5 to 40 parts per million (ppm)), duration (1 to 24 days), and mode of delivery. The 14 RCTs varied so widely that it was difficult to group them together in a way that took these important variables into account. For Key Question 1 (and Key Question 2), we viewed the aggregation of these 14 RCTs as providing data on a continuum of exposures to iNO (as listed above). This discussion of death and BPD includes all 14 RCTs that provide data for the variables we were charged with systematically reviewing: death or survival, BPD and the composite variable of death or BPD at 36 weeks PMA. Key Questions 4 and 5 explore data regarding subgroups and variations in administration of iNO, respectively.

Each of the 14 RCTs reported mortality data (three reported only death at 7 or 28 days), and 11 reported data on BPD (Table 2). Three studies focused on changes of oxygenation index (OI) at 2 to 24 hours after starting iNO therapy.^{60, 61, 65} Six RCTs reported using placebo gas in the control group and keeping NICU staff masked as to study arm assignment.^{34, 37, 39, 40, 58, 62} There were four multicenter RCTs and one single center RCT that had at least 100 infants per study

Table 2. Summary of outcomes for RCTs addressing KQ1

Outcomes	Number of studies	Total Sample size
Survival / Death	14 ^{34, 37, 39, 40, 58-67}	4754
BPD at 36 weeks PMA	12 ^{34, 37, 39, 40, 58-60, 62-65, 67}	2655
BPD other measures	11 ^{34, 37, 39, 40, 58-60, 62, 63, 65, 67}	3315
Death or BPD	12 ^{34, 37, 39, 40, 58-60, 62-65, 67}	3301

BPD = Bronchopulmonary dysplasia; PMA= Postmenstrual age

arm.^{37, 62} The findings of the 14 RCTs are discussed below by outcome variable: death/survival, BPD rate, severity of BPD and the composite variable of death or BPD (Appendix E, Evidence Tables 3 and 4; Table 2 and 3).

Survival and death. Each of the 14 RCTs reported mortality data, but there was some variation as to the time point cutoff they used for reporting death (e.g., 7 days, 28 days, 36 weeks PMA, death while in the NICU, or death while in the NICU or in the first 365 days for infants who had prolonged NICU stays). We assumed that death occurred in the NICU in the few studies that did not specify the time point cutoff they used for reporting death as they reported only NICU outcomes. One pilot study for a larger single center RCT focused on toxicity of iNO, and reported only death in the first seven days.⁶⁶ One study that focused on physiologic response to iNO reported death at seven and 28 days.⁶¹ For the INNOVO RCT, Field, 2005 reported death in the first day after birth, at two to six days, at seven to 27 days and at 28 days to one year corrected for degree of prematurity.⁶³ We included these three RCTs in the Evidence Table for death (Appendix E, Evidence Table 5). No matter how the 14 RCTs defined and reported death or survival, none of the 14 RCTs reported a statistically significant difference between iNO and control groups.

Our discussion and meta-analysis focuses on the 11 RCTs that report death by 36 weeks PMA or in the NICU, a specified variable we were asked to include in our systematic review. Six of the RCTs used the composite variable, death or BPD, as their primary outcome variable,^{37, 39, 40, 58, 64, 67} and two RCTs used survival without BPD at 36 weeks PMA as their primary outcome variable.^{34, 62} All three RCTs, Su 2008, Hascoet, 2005, and Srisuparp, 2002, that focused on immediate physiologic found no significant differences in mortality between the iNO and control groups.^{60, 61, 65} Survival to NICU discharge was the primary outcome in only one study, an early multicenter RCT published by Kinsella, 1999.⁵⁹ A lower than expected recruitment rate, in combination with an interim analysis that suggested they were unlikely to find a difference in survival, prompted them to terminate this trial early. The survival rates for the iNO group and controls were 25 percent versus 20 percent, respectively with a Relative Risk (RR) of 1.11 (95 percent confidence interval 0.70, 1.80). To make their data comparable to the other RCTs, we report not survival to NICU discharge, but their NICU mortality rates (i.e., 75 percent versus 80 percent) (Appendix E, Evidence Table 5).

The largest multicenter RCT (the EUNO trial), Mercier, 2010, was conducted at 36 centers in nine European countries.⁶² They enrolled 800 preterm infants born between 24 weeks and 28 6/7 weeks gestation with a BW at or above 500 g who were treated with surfactant and mechanical ventilation or continuous positive airway pressure (CPAP) for respiratory distress syndrome. Within 24 hours after birth, infants were enrolled and treated with low dose iNO (5 ppm) or placebo gas for a minimum of seven days. There was no statistically significant difference in survival at 36 weeks PMA between the iNO group and controls, 86 percent versus 90 percent, respectively, RR 0.74 (0.48, 1.15), adjusted for gestational age, baseline severity of illness, mode of ventilation and country. For comparison with the other RCTs, we present their data in Table 3

and our meta-analyses in terms of death by 36 weeks PMA, 14 percent versus 10 percent for iNO and control groups, respectively.

The second largest multicenter RCT, published by Kinsella, 2006, enrolled 793 preterm infants born at or before 34 weeks gestation with birth weight below 1250 g on mechanical ventilation in the first two days after birth.³⁷ Study infants were treated with low dose iNO (5 ppm) or placebo gas for 21 days or until extubation. The NICU mortality rates were 20 percent in the iNO group and 25 percent in the placebo group, RR 0.79 (0.61, 10.3) (p-value = 0.08) (Appendix E, Evidence Table 5).

Ballard, 2006, enrolled 582 infants born before 33 weeks gestation or less with birth weight below 1250 g who were on positive pressure ventilation (ventilator or CPAP) beyond the first week, seven to 21 days after birth.³⁴ Since preterm mortality is highest during the first week after birth, this RCT had the lowest mortality rates at 36 weeks PMA of all the RCTs of iNO in preterm infants, 5.4 percent in the iNO group and 6.3 percent in placebo controls. Mortality rates were only slightly higher after term, at 44 weeks PMA (6.9 percent versus 6.8 percent) (Appendix E, Evidence Table 5).

In the NICHD Neonatal Research Network's two RCTs of preterm infants born before 34 weeks gestation (BW 401 to 1500 g in the 2005 study and BW > 1500 g in the 2007 study), Van Meurs reported death before discharge to home or 365 days for preterm infants still hospitalized.^{39,40} For both RCTs, the Data Safety and Monitoring Committee noted higher than expected mortality rates, and recommended lowering the OI inclusion criteria. Despite this change to include infants with less severe respiratory failure, mortality rates for preterm infants with BW 400 to 1500 g were 52 percent for the iNO group versus 44 percent for placebo controls (RR 1.16 (0.96, 1.39)), adjusted for study center, BW group, and OI group.⁴⁰ As might be expected, mortality rates were somewhat lower for infants with birth weight above 1500 g, 36 percent in the iNO group versus 27 percent in controls (RR 1.26 (0.47, 3.41)) when adjusted for OI stratum.³⁹ (Appendix E, Evidence Table 5).

In the largest single center RCT with 207 infants born before 34 weeks gestation with BW below 2000 g, Schreiber, 2003 found no differences in death in the NICU or by six months: 15 percent for iNO versus 23 percent for placebo gas controls (RR 0.68 (0.38, 1.2)), adjusted for type of ventilation.⁵⁸ There were no statistically significant differences in NICU mortality in the Franco-Belgium, 1999 RCT (27 percent in the iNO group and 35 percent in controls), despite having an initial OI that was higher in the iNO group (median 20.2, interquartile range (IQR) 8.3) than in the control group (median 18.0, IQR 7.4)⁶⁰ Neither of two small single center RCTs that each enrolled 40 to 42 infants found statistically significant differences between the iNO and control groups: mortality was 20 percent versus 30 percent, respectively, as reported by Dani, 2006, and 50 percent versus 32 percent with RR 1.57 (0.76, 3.38) as reported by Subhedar, 1997^{64,67} (Appendix E, Evidence Table 5).

Table 3. Study design of randomized controlled trials of inhaled nitric oxide in preterm infants*

Author, year	Birth Years	Sample Size	Age	GA, wks	BW, gm	Respiratory	Exclusion Criteria [†]	Placebo/ Mask Staff	Start/ Max iNO, ppm	Duration of iNO, days	Sites, n

* All included infants were on either on a mechanical ventilator (MV) or continuous positive airway pressure (CPAP).

[†]All RCTs excluded infants with uncorrected bleeding problems, severe congenital heart disease or a decision to not provide full treatment (or contraindication of continuing intensive care).

[‡]high CLD score = chronic lung disease score that is composed of risk factors for chronic lung disease.⁸¹

a/AO₂ = alveolar/arterial oxygen ratio; BW – birth weight; CLD = chronic lung disease; CPCAP = continuous positive airway pressure; GA = gestational ages; IPH = intraparenchymal hemorrhage; MV = mechanical ventilator; OI = Oxygenation index; RDS = Respiratory distress syndrome; severe IVH = Intraventricular hemorrhage with ventricular dilation

There were no statistically significant differences (neither increase nor decrease) in NICU mortality rates with iNO in any of the individual fourteen RCTs that reported on death or survival. A meta-analysis of the 11 RCTs that reported death by 36 weeks PMA or in the NICU found no statistically significant differences between the iNO and control groups (RR 0.97 (0.82, 1.15)) (Figure 4).

The relatively high mortality rates for infants enrolled in most of these RCTs are striking. Regardless of group assignment, seven studies reported mortality rates as high as 25 percent to 65 percent,^{39, 40, 59-61, 63, 64} and another four reported mortality rates of 15 to 30 percent.^{37, 58, 65, 67} The Ballard, 2006 RCT reported the lowest mortality rates (5.4 percent for the iNO group and 6.3 percent for controls).³⁴ Most preterm infants who die in the NICU die during the first week after birth. The low mortality rates reported in Ballard, 2006 reflects a difference of study design in that they enrolled preterm infants on mechanical ventilation or CPAP at one and to three

Figure 4. Meta-analysis of 11 studies describing death at 36 weeks PMA or in the NICU

Figure 5. Meta-analysis of 10 studies describing death at 36 weeks PMA or in the NICU without Ballard, 2006

weeks after birth. We therefore removed the data from the Ballard RCT, and repeated the meta-analysis for the remaining ten RCTs. The results did not change: RR 0.98 (0.81, 1.17) (Figure 5). This sensitivity analysis confirmed no statistically significant effect of iNO compared to control on NICU death or survival to discharge from the NICU in preterm infants requiring positive pressure ventilation.

Bronchopulmonary dysplasia. The term bronchopulmonary dysplasia was introduced in 1967 when Northway reported a case series of preterm infants with respiratory distress syndrome (RDS) who developed a chronic lung disease with characteristic radiographic and pathologic features.⁸² Although it has always been defined clinically, the definition of BPD has evolved with neonatal intensive care.⁸³ The clinical, radiographic and pathologic features of BPD have changed as new technologies, medications and management strategies have been introduced, leading to dramatic reductions in gestational age specific neonatal mortality and a lowering of the limit of viability to now 22 to 24 weeks gestation. The evolution of BPD is reflected in its various definitions, including definitions based on persistent respiratory symptoms, radiographic features, and treatments (e.g., requiring supplemental oxygen at 28 days from birth, or a more severe BPD, requiring oxygen at 36 weeks PMA).

Twelve RCTs provide data on BPD at 36 weeks PMA, but there was some variation in how each RCT defined BPD. Six RCTs defined BPD simply as requiring supplemental oxygen at 36 weeks PMA.^{39, 40, 59, 60, 63, 67} One multicenter study³⁷ and three single center studies^{58, 64, 65} refined

the definition of BPD by adding the requirement of radiological evidence of BPD. Although there is general agreement that infants on mechanical ventilation or supplemental oxygen above 30 percent FiO₂ at 36 weeks PMA have BPD, some question whether infants on low flow nasal cannulas with a FiO₂ of 30 percent or less should be included in the BPD at 36 weeks PMA category.

Walsh published in 2003 an algorithm for physiologic BPD at 36 weeks PMA that includes an oxygen challenge test for infants on less than 30 percent FiO₂.⁸⁴ Four RCTs used these criteria for categorizing BPD at 36 weeks PMA.^{34, 39, 40, 62} Van Meurs, 2005 and 2007 reported that the rate of BPD as defined by Walsh was somewhat lower than the rate of BPD defined as on supplemental oxygen at 36 weeks PMA.^{39, 40} In the NICHD trial of infants born before 34 weeks gestation with birth weight below 1500 g, physiologic BPD rates, 50 percent in the iNO group and 60 percent in controls, RR 0.87 (0.68, 1.10), were lower than rates of BPD defined as requiring oxygen at 36 weeks PMA, 60 percent versus 68 percent, RR 0.90 (0.75, 1.08) (both RR were adjusted for study center, BW group and OI group).⁴⁰ In the NICHD RCT of infants with birth weight above 1500 g, the physiological definition classified one more infant treated with iNO as having BPD, and one less control infant as having BPD, resulting in BPD rates of 36 percent versus 40 percent respectively, RR 0.74 (0.26, 2.09) adjusted for OI stratum.³⁹ (Appendix E, Evidence Table 6). Using the physiologic definition at 36 weeks PMA, Mercier, 2010⁶² reported lower BPD rates, 24 percent in the iNO group compared to 27 percent in controls, RR 0.84 (0.58, 1.17), adjusted for gestational age, baseline severity of illness mode of ventilation, and country. Their inclusion criteria differed from two RCTs reported by Van Meurs^{39, 40} (Table 3) in their focus on gestational age (i.e., gestational age 24 to 28 6/7 weeks) rather than BW and lower severity of initial illness (mechanical ventilation with FiO₂ at or above 30 percent).

The twelve RCTs also vary as to the denominator used when calculating rate of BPD at 36 weeks PMA: Five used the total number of infants in each group,^{34, 63-65, 67} and seven RCTs used the number of *survivors* in each group.^{37, 39, 40, 58-60, 62, 85} The small single center Subhedar, 1997 RCT reported BPD rates both for the total group (50 percent for the iNO group versus 64 percent for controls) and for survivors (100 percent versus 90 percent).⁶⁴

Dani, 2006 noted that infants treated with iNO had half the rate of BPD at 36 weeks PMA than the controls (30 percent versus 60 percent, respectively, p-value = 0.067, BPD rate for the total group).⁶⁷ An unplanned interim analysis revealed a statistically significant reduction in their primary outcome, death or BPD (p-value = 0.016). On the recommendation of their consulting statisticians and two independent observers, the study was terminated early, with enrollment of only 40 of the anticipated 52 infants. Another small single center RCT found no statistically significant differences in rate of BPD at 36 weeks PMA (31 percent for the total iNO group and 33 percent for the total control group).⁶⁵ Field, 2005 reported that 26 of 55 infants in the iNO group and 15 of 53 infants in the control group had BPD at 36 weeks PMA, 47 percent versus 28 percent. Ballard, 2006 reported rates of BPD at 36 weeks PMA for the total iNO group as compared with the total placebo gas control group: 50.7 percent versus 56.9 percent, respectively (Appendix E, Evidence Table 6).

In addition to the Mercier and two Van Meurs NICHD Neonatal Research Network RCTs, Kinsella, 2006 reported BPD rates using as denominator the number of infants alive at 36 weeks PMA^{37, 39, 40} There was no statistically significant differences between the iNO and placebo gas control groups, 65 percent versus 68 percent, respectively, RR 0.96 (0.86, 1.09). Using the number of survivors as denominator, Kinsella, 1999 and Schreiber, 2003 reported differences in

rates of BPD at 36 weeks PMA that were not statistically significant.⁵⁸ Kinsella, 1999 reported that 60 percent of survivors in the iNO group had BPD at 36 weeks PMA as compared with 80 percent of control survivors.⁵⁹ Schreiber, 2003 reported that 39 percent of iNO group survivors compared to 53 percent of control group survivors had BPD at 36 weeks PMA, RR 0.74 (0.53, 1.03) (Figure 6).⁵⁸ (Appendix E, Evidence Table 6).

Despite variations in how BPD was defined and calculated, there were no statistically significant differences in rates of BPD at 36 weeks PMA between the iNO group and controls in any of the RCTs. Subhedar, 1997⁶⁴ demonstrated how drastically BPD rates can differ when they are calculated using survivors as compared with the total group as denominator. For this reason, we did not do a meta-analysis with all 12 RCTs. We included eight studies in a meta-analysis of the rate of BPD at 36 weeks PMA in *survivors*. The small difference was not statistically significant (RR 0.93 (0.86, 1.003)) (Figure 6) (Appendix E, Evidence Table 6).^{37, 40, 58, 59, 64}

Figure 6. Meta-analysis of eight studies describing BPD at 36 weeks PMA among survivors

Other measures of severity of bronchopulmonary dysplasia. Although the most accepted BPD definition is based on being on supplemental oxygen at 36 weeks PMA, there are other measures of severity of lung disease (e.g., duration of mechanical ventilation and oxygen supplementation, treatment with medications for lung disease), and other time points for reporting the need for mechanical ventilation of supplemental oxygen (e.g., at 40 weeks PMA, 44 weeks PMA and NICU discharge). We found no RCTs that reported number of infants on mechanical ventilation at 36 weeks PMA.

Ballard, 2006 reported statistically significantly fewer infants in the iNO group than controls remained in the hospital, and on mechanical ventilation, nasal continuous positive airway pressure (CPAP) or supplemental oxygen at 40 weeks PMA (p-value = 0.01), and at 44 weeks PMA (p-value = 0.03).³⁴ At 40 weeks PMA (i.e., full term), six percent in the iNO group and 10 percent of controls were hospitalized and on mechanical ventilation, and 22 percent versus 29 percent were hospitalized and on supplemental oxygen. Kinsella, 1999 reported that 54 percent of infants in the iNO group were discharged home on oxygen as compared with 80 percent of control infants, RR 0.65 (0.41, 1.02).⁵⁹ In contrast, only nine percent of all infants in each group were discharge home on supplemental oxygen in Field, 2005.⁶³

Kinsella, 2006 reported no differences between the iNO group and controls in proportion of infants ever treated with postnatal corticosteroids (60 percent versus 56 percent).³⁷ There were no statistically significant differences in proportion of survivors at 36 weeks PMA who were on bronchodilators (20 percent versus 20 percent), corticosteroids (15 percent versus 12 percent) or diuretics (37 percent versus 38 percent). In Franco-Belgium, 1999 there were also no statistically significant differences between the 29 survivors in the iNO group who were treated with steroids (54 percent versus 72 percent) or beta-mimetics (21 percent versus 39 percent) than the 29 control survivors.⁶³ Field, 2006 reported that 40 percent and 34 percent of the iNO versus control group were treated with corticosteroids⁶³ (Appendix E, Evidence Table 6). Eight RCTs reported mean duration of supplemental oxygen, mechanical ventilation or CPAP.^{39, 40, 58, 60, 62, 63, 65, 67} Dani, 2006 reported a statistically significant lower mean duration of supplemental oxygen reached statistical significance for all infants in the iNO compared to all in the control group (47.3+/-39.4 versus 69.4+/-30.2, p-value = 0.05), but no statistically significant differences in mean days of mechanical ventilation or CPAP.⁶⁷ Two other RCTs found no statistically significant differences between the total iNO group and controls in mean duration of mechanical ventilation^{60, 65} nor mean duration of supplemental oxygen.⁶⁰ (Appendix E, Evidence Table 6). The largest multicenter RCT published in 2010 by Mercier reported no statistically significant differences in mean duration of mechanical ventilation between the iNO group and controls, 44+/-26 versus 45+/-29, respectively, p-value = 0.68, but did not specify whether these data were for the total groups or survivors.⁶² Three RCTs reported mean duration of supplemental oxygen or mechanical ventilation in *survivors*.^{39,40, 58} Van Meurs, 2007 RCT of preterm infants with birth weight above 1500 g, the mean duration of mechanical ventilation was 8.7+/-5.4 days for the nine survivors in the iNO group and 16.8+/-13.9 for the 11 controls (p-value = 0.08).³⁹ In their RCT of preterm infants with birth weight 400 to 1500 g, there were no statistically significant differences between the iNO and control groups in mean duration of mechanical ventilation (39+/-45 versus 47+/-53) or supplemental oxygen (84+/-63 versus 91+/-61).⁴⁰ In Schreiber, 2003, the median duration of mechanical ventilation was 16 days for the iNO group (the interquartile range was 8 to 48) and 28.5 days (IQR 8 to 48) for controls p-value = 0.19.⁵⁸ (Appendix E, Evidence Table 6).

As a part of their analyses of costs and resource utilization, Field, 2005 reported data regarding mechanical ventilation and supplemental oxygen for infants who survived and for the total group.⁶³ Median (interquartile range) for days on mechanical ventilation after randomization was 7.0 (2.0, 28.0) for all infants in the iNO group versus 4.0 (1.0, 9.0) in all controls, and 15.0 (6.0, 28.0) for survivors in the iNO group versus 12.0 (5.0, 36.0) in surviving controls. The data for days on supplemental oxygen after randomization were similar.⁶³ (Appendix E, Evidence Table 6).

Of the eight RCTs that reported various measures of severity of BPD, only two reported differences between the iNO and control groups that approached statistical significance, and both favored iNO. Ballard, 2006 reported a statistically significant reduction in hospitalization and respiratory support at 40 and 44 weeks PMA with iNO (p-value = 0.01 and p-value = 0.03, respectively).³⁴ Dani, 2006 reported a lower duration of supplemental oxygen with iNO (p-value = 0.05).⁶⁷ There are insufficient data to perform a meta-analysis for any measure of severity of BPD due to lack of uniformity in definitions used. Although a number of RCTs reported duration of mechanical ventilation and/or supplemental oxygen, they varied as to whether they used mean +/- standard deviation or median (interquartile range), and whether the data were calculated for the total group or only for survivors.

Death or bronchopulmonary dysplasia at 36 weeks PMA. The composite outcome of death or BPD at 36 weeks PMA was reported in 11 RCTs: it was the primary outcome variable for six RCTs³⁹; its complement, survival without BPD at 36 weeks PMA, was the primary outcome variable in the Mercier, 2010 RCT^{34, 62}; in two RCTs the primary variable was OI at a specified time^{60, 65}; in one RCT the primary outcome variable^{34, 37, 40, 58, 64} was survival to discharge from the NICU⁵⁹; and for one RCT the primary outcome variable was death or severe neurodevelopmental impairment.^{59, 63} In one multicenter RCT and two single center RCTs, there were statistically significant differences between the iNO group and controls in the composite outcome of death or BPD.^{34, 58, 67} All eleven RCTs were included in our meta-analysis. (Appendix E, Evidence Table 7).

Ballard, 2006 found a statistically significant benefit in their primary outcome, survival without BPD at 36 weeks PMA, for the iNO group compared to placebo controls, 44 percent versus 37 percent, RR 1.23 (1.01, 1.51).³⁴ The number needed to treat was 14. Although their study sample was similar to other RCTs (birth before 33 weeks gestation with birth weight at or below 1250 g), infants were enrolled later than in other studies (at 7 to 21 days, compared to within the first week), and the minimum duration of treatment for the Ballard study was 21 days. For comparison with the other RCTs, we used the complement composite variable, rates of death or BPD at 36 weeks PMA, 56 percent of the iNO group versus 63 percent of the placebo control group) in Appendix E, Evidence Table 7 and Figure 7.

Schreiber, 2003, the largest single center trial, reported a statistically significant difference in rate of death or BPD.⁵⁸ In the iNO group (n = 105), 49 percent died or developed BPD compared to 64 percent in the placebo control group (n = 102), RR 0.76, (0.60, 0.97). This RCT enrolled infants born before 34 weeks gestation as other RCTs but with birth weight below 2000 g, and they treated study infants with iNO for seven days (Appendix E, Evidence Table 7).

The other single center RCT that found a statistically significant difference between the iNO group and controls in the outcome of death or BPD was reported by Dani, 2006.⁶⁷ This RCT was stopped early (n = 40) because an unplanned interim analysis found a statistically significant difference (p-value = 0.02) in death or BPD, their primary outcome. Only 50 percent of infants in the iNO group died or developed BPD, compared to 90 percent of infants in the control group,

RR 0.11 (0.02, 0.61). In this study, the controls were not treated with placebo gas but received standard care and NICU staff was not masked as to study status. The mean duration of treatment with iNO was 98.5 +/- 21.4 hours (4.1 days) (Appendix E, Evidence Table 7).

The largest multicenter RCT published in 2010 by Mercier reported no statistically significant difference between 395 infants in the iNO group compared to 400 in the placebo gas control group in their primary outcome variable, survival without BPD at 36 weeks PMA.⁶² They used low dose 5 ppm iNO for seven to 21 days and the physiologic definition of BPD, as published in 2003 by Walsh.⁵⁷ Sixty-five percent of the infants in the iNO group and 66 percent of infants in the placebo gas control group survived without BPD at 36 weeks PMA, RR 1.05 (0.78, 1.43). For comparison with other RCTs, we use the complement combined variable death or BPD at 36 weeks PMA, 35 percent versus 34 percent, respectively (Appendix E, Evidence Table 7 and Figure 7).

Just as they found no statistically significant differences in mortality or BPD rates, the two Van Meurs Neonatal Research Network RCTs, the large multicenter Kinsella, 2006 RCT, and Subhedar's small single center RCT found no statistically significant differences in the composite variable of death or BPD at 36 weeks PMA.^{37, 39, 40, 64} Both NICHD trials were terminated at the second interim data analysis of this study, at the recommendation of their data safety monitoring committee, based on no statistically significant differences in death or BPD and concerns about significantly higher rates of severe intracranial hemorrhage or periventricular leukomalacia (PVL) in the larger RCT.^{39, 40} Rate of death or BPD at 36 weeks PMA was 80 percent for the iNO group and 82 percent for controls, RR 0.97 (0.86, 1.06) adjusted for study center, birth weight group and OI group.⁴⁰ The NICHD trial of infants birth weight above 1500 g reported that rate of death or BPD at 36 weeks PMA was 50 percent for the iNO group and 60 percent for controls, RR 0.80 (0.43, 1.48) adjusted for OI.³⁹ The rate of death or BPD in the large Kinsella, 2006 multicenter RCT was 72 percent in the iNO group compared to 75 percent in controls, RR 0.95 (0.87, 1.03).³⁷ Kinsella, 1999, a trial that included infants with more severe respiratory failure, reported much higher rates of death or BPD at 36 weeks PMA, 77 percent versus 91 percent, RR 0.85 (0.70, 1.03), but no significant differences between groups.⁵⁹ Subhedar, 1997 reported even higher rates of death or BPD at 36 weeks PMA, 95 percent in the iNO group and 100 percent in controls, RR 1.04 (0.92, 1.19).⁶⁴ (Appendix E, Evidence Table 7).

Figure 8. Meta-analysis of 10 studies describing death or BPD at 36 weeks PMA, without Ballard, 2006

Conclusion

Neither our meta-analysis nor any of the fourteen RCTs found any statistically significant differences in death in the NICU or survival to NICU discharge with iNO. Similarly, there were no statistically significant differences in any of the 12 RCTs that reported rates of BPD at 36 weeks PMA. Our meta-analysis of eight RCTs that reported rate of BPD at 36 weeks PMA for survivors did not find a statistically significant difference between the iNO or control groups, though most of these studies favored the iNO group. Two of eight RCTs that reported other pulmonary outcomes reflecting severity of BPD reported statistically significant findings in favor of iNO: a reduction in rates of hospitalization and respiratory support at 40 and 44 weeks PMA,³⁴ and a statistically significant reduction in mean duration of supplementary oxygen.⁶⁷ Three of 11 RCTs reported a statistically significant reduction of the composite variable, death or BPD at 36 weeks PMA or its complement, improved survival without BPD at 36 weeks PMA.^{34, 58, 67} There was a small but statistically significant reduction in favor of iNO in our meta-analysis of all 11 RCTs that reported data for the composite variable, death or BPD at 36 weeks PMA. Ballard, 2006 is considered by some as different from the other studies in terms of study design (i.e., not enrolling or initiating treatment until a week or more after birth, and a minimum treatment duration of 21 days), and it had the lowest mortality rate of all 14 RCTs. Excluding data from the Ballard, 2006 and rerunning the meta-analysis resulted in the same effect estimate but a wider confidence interval that included 1. A meta-analysis with all 11 trials may provide a more

complete picture of the available evidence, when considering the effect of iNO in a continuum of exposure at various postmenopausal ages. When death or BPD at 36 weeks PMA is viewed in terms of its complement, the pooled estimate of risk favors iNO with a small but statistically significant improvement in survival without BPD at 36 weeks PMA by seven percent. This finding leads to questions about short term risks, longer term neurodevelopmental, pulmonary and other health outcomes, whether iNO is more effective in certain subgroups, and optimal doses, and methods of drug administration, which are discussed in Key Questions 2, 3, 4 and 5.

Key Question 2: Are there short term risks of iNO therapy among premature infants who receive respiratory support?

Major Findings

- There is insufficient evidence of a neuroprotective effect of iNO in preterm infants.
- There is no evidence that treatment of preterm infants with iNO influences the rates of other complications of prematurity, including patent ductus arteriosus (PDA), sepsis, necrotizing enterocolitis (NEC), severe retinopathy of prematurity (ROP), pulmonary hemorrhage, or air leaks.
- No study reported accumulation of toxic levels of methemoglobin or nitrogen dioxide.

Detailed Analysis

Preterm birth requires infants to utilize organ systems that are not yet fully mature.⁸⁶ The many complications of prematurity are multifactorial in etiology, but the highest risk factor is degree of prematurity. Infants born at 22 to 23 weeks gestation, the lower limit of viability, have the highest risks of all the complications of prematurity. Many biologic and environmental risk factors have been identified, and often overlap. For example, inflammation is associated with preterm birth and the development of BPD, white matter brain injury, necrotizing enterocolitis (NEC), and retinopathy of prematurity (ROP). How iNO exposure will influence the incidence of these complications of prematurity has been a major concern. Laboratory data suggest iNO may increase or decrease inflammation, cause bleeding by interfering with platelet aggregation and adhesion, and/or lead to accumulation of toxic substances (e.g., methemoglobin, formed by reaction of NO with hemoglobin, or nitrogen dioxide).

All 14 RCTs that compared treatment with iNO to standard treatment in preterm infants reported data regarding short term risks, including methemoglobin levels, and many complications of prematurity. The complications of prematurity we review in this section include brain injury, patent ductus arteriosus (PDA), sepsis, NEC, ROP, pulmonary hemorrhage, air leak, and pulmonary hypertension. Evidence of brain injury, obtained by serial head ultrasounds, includes intraventricular hemorrhage (IVH), intraparenchymal hemorrhage (IPH), hydrocephalus, periventricular leukomalacia (PVL), and other signs of white matter injury, including ventriculomegaly (Appendix E, Evidence Tables 3 and 4; Table 4). Meta-analyses were performed for all short term outcomes and are presented in a table at the end of this section. Not all RCTs reviewed in the text are included in the meta-analyses because of differences in the denominators across studies (e.g., all infants enrolled versus only survivors), and in the definition

Table 4. Summary of outcomes for RCTs addressing KQ2

Outcomes	Number of studies	Total Sample size
Brain Injury	13 ^{65, 34, 37, 39, 40, 58-62, 64, 66, 67}	2936
PDA	11 ^{34,37, 58, 59, 61-67}	2870
Sepsis	8 ^{34,37, 58, 62, 63, 65-67}	2958
NEC	8 ^{34, 37, 58, 61, 62, 64, 65, 67}	2683
ROP	8 ^{34, 37, 39, 40, 58, 59, 63, 64}	2025
Pulmonary hemorrhage	7 ^{37, 58, 59, 62-65}	2089
Air leak or pneumothorax	10 ^{37, 39, 40, 58, 59, 62-66}	2361
Methemoglobinemia	12 ^{34, 37, 39, 40, 58, 59, 62-67}	3190

PDA = Patent ductus arteriosus, NEC = Necrotizing enterocolitis, ROP = retinopathy of prematurity, treated

of the condition (e.g. any air leak versus only new air leak occurring after randomization). We grouped trials for analysis of each condition based on similar measurement characteristics, and indicate which trials were included in the table.

Evidence of brain injury. The nomenclature that describes injury to the preterm infant's brain has changed since the publication of the earliest RCTs of iNO in preterm infants in 1997. Severity of IVH was often reported using the grading system proposed by Papile, 1978.⁸⁷ Grade 1 is a germinal matrix hemorrhage (GMH), grade 2 is blood in the ventricle but not filling or dilating the ventricle, grade 3 is a large amount of blood in the ventricle and ventricular dilation, and grade 4 is blood in the brain parenchyma, i.e., intraparenchymal hemorrhage (IPH). In terms of its association with neurodevelopmental outcome, GMH is the most benign form of IVH, and despite the IVH grading system, it does not denote blood in the ventricle. In the very immature infant's brain, the germinal matrix is a rich capillary network adjacent to the lateral ventricles, and very vulnerable to injury. Hemorrhage in the germinal matrix can extend into the ventricle, causing an intraventricular hemorrhage (IVH). The hemorrhage can also originate in the choroid plexus of the ventricle, and extend into the ventricle, causing an IVH. Blood in the ventricle may fill the ventricle and dilate it (Papile grade 3 IVH), or blood may be present in the ventricle with no ventricular dilation (Papile grade 2 IVH). However, there may be other causes of enlarged ventricles (called ventriculomegaly). Resorption of injured brain parenchyma can produce ventriculomegaly, as well as cysts in the brain parenchyma. Intraparenchymal hemorrhage (IPH) is more often caused by hemorrhagic infarction of brain tissue than by blood from an IVH extending into the brain parenchyma (Papile grade 4 IVH). An IPH may be due to blood filling the ventricles and compressing the venous network, or may be an injury to the brain that is unrelated to IVH. Periventricular leukomalacia (PVL) is seen when injured brain tissue, especially white matter, is resorbed and replaced by fluid. PVL manifests as small cysts, large cysts, larger ventricles with irregular borders, or any combination of these findings. PVL may be in the frontal, parietal or occipital lobes, and it may be on one side (unilateral) or bilateral. Some preterm infants who did not have an IVH develop ventriculomegaly due to resorption of injured brain. IVH with ventriculomegaly (Papile grade 3 IVH), IPH, PVL with or without ventriculomegaly are each associated with a high risk of neurodevelopmental impairment (NDI).⁸⁷

Thirteen RCTs compared rate of brain injury on serial head ultrasounds in the iNO and control groups.^{34, 37, 39, 40, 58-62, 64-67} Brain injury may occur in utero, during labor and delivery, and immediately after birth, and is common in preterm infants on mechanical ventilation. Studies that compared head ultrasounds before treatment with head ultrasounds obtained after treatment can best determine whether exposure to iNO has a toxic or neuroprotective effect on brain injury. Few studies were able to obtain pretreatment head ultrasounds due to logistical problems. Only

four RCTs obtained head ultrasounds at or before enrollment, and compared these to serial ultrasounds obtained during the remainder of the infant's NICU hospitalization^{34, 37, 59, 64} (Appendix E, Evidence Table 8). The other seven RCTs did not obtain head ultrasounds before study entry.

Kinsella, 2006, enrolled 420 preterm infants born at and before 34 weeks gestation with a birth weight (BW) of 500 to 1250 g on mechanical ventilation within the first two days after birth, and treated them with low dose iNO (5 ppm) or placebo gas for 21 days.³⁷ Head ultrasounds at study entry revealed no statistically significant differences between the iNO and placebo control groups in rates of GMH or IVH without ventriculomegaly (Papile grades 1 or 2 IVH, 18.4 percent versus 21.9 percent, respectively) or of IVH with ventriculomegaly (Papile Grade 3 IVH) or IPH (6.1 percent versus 6.6 percent, p-value = 0.41). Infants with GMH, IVH with or without ventriculomegaly or IPH (Papile grades 1 to 4 IVH) at study entry were reported in the outcome data if their condition worsened during or after treatment. Ultrasonographers were masked as to treatment category. They found no statistically significant differences of IVH with ventriculomegaly or IPH between iNO and placebo control groups, 12.3 percent versus 16.0 percent, RR 0.77 (0.54, 1.09) or of ventriculomegaly, 5.2 percent versus 8.9 percent, RR 0.58 (0.37, 1.01), p-value = 0.05. There was a statistically significant reduction of PVL in infants in the iNO group (5.2 percent) compared to placebo controls (9.0 percent), RR 0.58 (0.33, 1.00), p-value = 0.048. The infants in the iNO group had a statistically significant reduction in the rate of the composite variable of IVH with ventriculomegaly (Papile grade 3 IVH), IPH, PVL or ventriculomegaly than placebo controls, 17.5 percent versus 23.9 percent respectively, RR 0.73 (0.55, 0.98), p-value = 0.03 (Appendix E, Evidence Table 8).

Ballard, 2006 enrolled infants with a BW at or below 1250 g on ventilator support or CPAP at seven to 21 days, and treated them for a minimum of 21 days.³⁴ Most preterm infants develop IVH or IPH within the first seven days after birth. Head ultrasounds were performed before enrollment and during and/or after administration of iNO or gas placebo. At baseline, there were no statistically significant differences in rate of unilateral IVH with ventriculomegaly or IPH, 11.9 percent versus 15.6 percent respectively; infants with bilateral IVH with ventriculomegaly or IPH were excluded. There were no differences between the iNO group and controls in the evolution of neurologic findings on head ultrasounds, 5.0 percent versus 4.1 percent, RR 1.21 (0.53, 2.76). (Appendix E, Evidence Table 8).

Two smaller RCTs were also able to perform head ultrasounds before initiating treatment. Kinsella, 1999 found that at study entry, 15 percent in the iNO group and 19 percent of controls had IVH with or without ventriculomegaly or IPH (Papile's grades 2 to 4 IVH).⁵⁹ There were no statistically significant differences in rate of IVH or IPH with or without ventriculomegaly in survivors in the iNO group compared to controls, 28 percent versus 33 percent. They reported no statistically significant differences in rates of new or higher grade of IVH or IPH (44 percent versus 42 percent)⁵⁹ (Appendix E, Evidence Table 9). In Subhedar, 1997, 42 infants born before 32 weeks gestation were enrolled at four days after birth and randomized to iNO or a control group.⁶⁴ They obtained head ultrasounds at baseline and at weekly intervals for a month. No infant in either the iNO or the control group had an extension of an existing IVH⁶⁴ (Appendix E, Evidence Table 8).

The small pilot RCT reported by Srisuparp, 2002 is the only RCT whose primary outcome variable was IVH with ventriculomegaly (Papile grade 3 IVH or IPH).⁶⁶ They were unable to obtain head ultrasounds in all infants before study entry, however, as most were enrolled on the

day of birth. They found no statistically significant differences between the iNO and control groups in brain injury, 25 percent versus 28 percent respectively.

Schreiber, 2003, enrolled 207 infants born before 34 weeks gestation with BW below 2000 g on mechanical ventilation for respiratory distress syndrome during the first week after birth.⁵⁸ After randomization to the iNO or the gas placebo group, infants in the iNO group were given iNO at 10 ppm for 12 to 24 hours then 5 ppm for six days. They did not obtain head ultrasounds before study entry; all ultrasounds were interpreted by a pediatric radiologist masked to treatment assignments. Infants in the iNO group had statistically significantly lower rates of the composite variable, IVH with ventriculomegaly (Papile grade 3 IVH), IPH or PVL than placebo controls, 12.4 percent versus 23.5 percent respectively, (RR 0.53 (0.28, 0.98), p-value = 0.04). They found no statistically significant differences in the rate of posthemorrhagic hydrocephalus, 11.4 percent versus 9.8 percent, RR 1.17 (0.53, 2.58). (Appendix E, Evidence Table 8).

The secondary hypothesis of the Van Meurs 2005 RCT of infants born before 34 weeks gestation with BW 401 to 1500 g who had severe respiratory failure was that iNO would not increase the incidence of the composite variable, IVH with ventriculomegaly (Papile grade 3 IVH), IPH or PVL.⁴⁰ This study was terminated after the second planned analysis because of a higher rate of the composite brain injury variable in the iNO group than in controls reached statistical significance. However, when outcomes were analyzed for all 420 enrolled infants (the plan was for 440 infants) there were no statistically significant differences in rates of the composite brain injury variable (Papile grade 3 IVH, IPH or PVL) whether ultrasounds were read by each center's local radiologists, 39 percent in the iNO group and 32 percent in controls, RR 1.25 (0.95, 1.66); or when they were read by a central masked reader after the study was terminated, 37 percent versus 38 percent, RR 0.97 (0.74, 1.27). Infants enrolled in this RCT had similar BW as in Kinsella 2006, and both RCTs had lower BW than in Schreiber, 2003.^{37 58} However, infants in Van Meurs, 2005 were sicker than those in either Schreiber, 2003 or Kinsella, 2006, with OI 22 to 23 compared to five to seven at enrollment (Appendix E, Evidence Table 8).

In a meta-analysis of five RCTs^{34, 37, 39, 40, 58} that reported the composite brain injury variable, defined by a combination of IVH with ventriculomegaly, IPH, or PVL (Kinsella, 2006 included ventriculomegaly as a separate variable), there was no statistically significant difference between infants treated with iNO and controls, RR 0.86 (0.58, 1.29). Results were unaffected by removal of the Ballard trial,³⁴ a study that enrolled infants much later than the other trials included in the analysis and reported only new or worsening brain injury: RR 0.79 (0.50, 1.27) (Figure 9). There was a substantial degree of heterogeneity among the five studies in this meta-analysis of brain injury ($I^2 = 0.657$). The two RCTs with the lowest RR of brain injury (Van Meurs, 2007 and Schreiber, 2003) differed from the other studies by including larger preterm infants, with BW above 1500 g.^{39, 58} Brain injury tends to occur during the first week after birth and is associated with cardiovascular instability in sick preterm infants. We can speculate that the larger preterm infants derived greater benefit from the effect of iNO on cardiovascular stability, as is seen with more mature full term infants. Smaller, more preterm infants may not benefit as much from this effect, due to immature autoregulation of their cerebral blood flow.

Figure 9. Meta-analysis of five studies describing brain injury

Similarly, a meta-analysis of RCTs that reported the incidence of PVL showed no difference between the iNO and control groups, RR 0.78 (0.37, 1.62) (Table 5).

In summary, one large multicenter RCT and one large single center RCT found a lower rate of brain injury (IVH with ventriculomegaly, IPH, PVL, +/- ventriculomegaly) in infants treated during the first week after birth with iNO compared to placebo controls. Another large multicenter RCT was terminated early for concern that the iNO group had a higher rate of IVH with ventriculomegaly, IPH or PVL than controls, but on final analyses, there were no statistically significant differences between the iNO and control groups. All the other RCTs found no statistically significant differences between the iNO and control groups in rates of all IVH (Papile grades 1 to 4), IVH with ventriculomegaly IPH, PVL, hydrocephalus, or combinations of these variables. What makes these findings important is that these signs of brain injury on serial head ultrasounds in the NICU are some of the best predictors for neurodevelopmental impairment in preterm infants. Key Question 3 addresses more long term outcomes, at a year or more, including cerebral palsy (CP), cognitive abilities, and neurodevelopmental impairments.

Patent ductus arteriosus. In the fetus, the ductus arteriosus allows most of the blood to bypass the lungs (and circulate through the placenta). In preterm infants, especially the most immature, failure of this duct to close can interfere with their transition to extrauterine life and lead to heart failure. By altering pulmonary blood flow, iNO may influence duct closure. Eleven RCTs described in 12 articles compared incidence of PDA in the iNO group and controls.^{34, 37, 58,}

^{59, 61-67, 78} Some trials reported only those infants who underwent surgical ligation of their PDA, and others included all infants diagnosed with PDA, whether they were treated medically or surgically. Kinsella, 2006 reported rates of symptomatic PDA that were medically treated (54.0 percent in the iNO group versus 53.7 percent of controls), and rates of PDA treated with surgical ligation (21.6 percent versus 21.8 percent).³⁷ None of the eleven RCTs (Appendix E, Evidence Table 9) or a meta-analysis (RR 1.01(0.86, 1.19); Table 5) found a statistically significant difference in incidence of PDA between the iNO groups or controls.

Sepsis. Eight RCTs reported data on infants who developed sepsis. Schreiber, 2003 reported the incidence of sepsis diagnosed after the first day, to distinguish between infants who were septic at birth from those that developed sepsis during their NICU course.⁵⁸ Some studies reported sepsis only if the infant's blood culture was positive.^{34, 63, 66, 67} None of the eight RCTs^{34, 37, 58, 62, 63, 65-67} that reported rate of sepsis found statistically significant differences between their iNO and control groups (Appendix E, Evidence Table 9). All eight trials were included in a meta-analysis that found no difference in the development of sepsis between infants treated with iNO and controls, RR 1.06 (0.95, 1.18) (Table 5).

Necrotizing enterocolitis. NEC is an acute inflammation of the intestines that can lead to intestinal perforation, surgical resection of injured bowel and placement of an ostomy. Bowel perforation is generally associated with sepsis, and treatment consists of intravenous antibiotics, bowel rest, parenteral nutrition, and cautious refeeding. NEC can therefore have an impact on subsequent health and growth. Eight RCTs reported in nine articles^{34,37, 58, 61, 62, 64, 65, 67,78} compared the incidence of NEC in iNO and control groups. Ballard, 2006 was the only study to distinguish between NEC treated medically and infants who needed surgery. They found no statistically significant differences in incidence of NEC, 7.8 percent in the iNO group versus 6.6 percent in controls, RR 1.17 (0.64, 2.13) or NEC requiring surgery (3.4 percent in the iNO group and 2.8 percent in controls, RR1.20 (0.46, 3.13).³⁴ None of the eight RCTs (Appendix E, Evidence Table 9) nor our meta-analysis (RR 1.23 (0.94, 1.62; Table 5)) found any statistically significant differences in NEC between iNO and control groups.

Table 5. Meta-analyses of short term risks of iNO therapy

Variable	Studies included	Pooled RR	95 % CI
Brain injury, IVH, IPH and/or PVL	Ballard, 2006 ³⁴ Kinsella, 2006 ³⁹ Schreiber, 2003 ⁵⁸ Van Meurs, 2005 ⁴⁰ Van Meurs, 2007 ³⁹	0.86	0.58, 1.29

Table 5. Meta-analyses of short term risks of iNO therapy (continued)

*Studies excluded: Hascoet,⁶¹ outcomes measured at 28 days; Dani⁶⁷ PDA diagnosed prior to treatment

†Studies excluded: Hamon⁷⁸ and Hascoet⁶¹ outcomes measured at 28 days

‡Included only studies that excluded infants with bleeding disorders from enrollment.

§ Included only studies where all enrolled infants were considered in the denominator.

Retinopathy of prematurity. Retinopathy of prematurity is a neovascular retinal disorder, which can result in severe visual impairment. Serial eye examinations determine whether ROP is present as the retina is vascularized, and if it is progressing. Visual outcomes are improved for severe ROP, especially if there are dilated, tortuous blood vessels in the posterior pole of the eye (i.e. plus disease) with laser surgery. Eight RCTs report the incidence of severe ROP treated with laser surgery.^{34, 37, 39, 40, 58, 59, 63, 64} Ballard, 2006 found a high incidence of any degree of ROP in their high risk study population, 83.7 percent in the iNO group and 81.9 percent in controls, RR 1.00 (0.93, 1.07).³⁴ Their incidence of severe ROP requiring treatment was 24.5 percent in the iNO group versus 23.6 percent in controls, RR 0.97 (0.72, 1.31). This is similar to the incidence of ROP requiring treatment in the other seven RCTs, and none found statistically significant differences between iNO and control groups (Appendix E, Evidence Table 9). A meta-analysis confirmed no statistically significant difference in ROP between infants treated with iNO and controls, RR 1.01 (0.82, 1.24; Table 5).

Pulmonary complications. In Key Question 1, we addressed the primary pulmonary complication of prematurity, BPD. In this section, we report other pulmonary complications: pulmonary hemorrhage, air leak or pneumothorax, pulmonary hypertension or right heart failure. An important consideration is whether infants were excluded from studies if they had evidence of bleeding or air leak before entry into the study. If they were not excluded, the most meaningful data are the rate of pulmonary hemorrhage or air leak once entered into the study. Five RCTs, described in six articles, excluded infants with low platelets or bleeding problems,^{40, 61, 63, 65, 67, 62} and four excluded infants with severe intracranial or pulmonary hemorrhage.^{34, 37, 60}

Seven RCTs report data on pulmonary hemorrhage. Whether they excluded infants with bleeding problems^{37, 63, 65, 74} or not^{58, 59, 64} they did not find any statistically significant differences between iNO and control groups in rates of pulmonary hemorrhage (Appendix E, Evidence Table 9). Our meta-analysis with trials that excluded infants with bleeding problems showed no difference in pulmonary hemorrhage between iNO treated infants and controls, RR 0.89 (0.60, 1.33) (Table 5).

Ten RCTs reported rates of air leak or pneumothorax, and none found any statistically significant differences between the iNO and control groups.^{37, 39, 40, 58, 59, 62-66} Schreiber, 2003 reported pneumothorax and pulmonary interstitial emphysema separately, finding no statistically significant differences in rate of pneumothorax (10.5 percent versus 16 percent, respectively) or pulmonary interstitial emphysema (27 percent versus 34 percent, respectively).⁵⁸ The rates of air leak varied from a low of four to six percent^{58, 64, 65} to as high as 35 to 38 percent^{40, 63} (Appendix E, Evidence Table 9). Our meta-analysis with trials that included all infants in the denominator also found no difference in the risk of air leak between the iNO treated infants and controls, RR 0.96 (0.71, 1.28) (Table 5).

The only trial that reported pulmonary hypertension as an outcome variable documented 50 percent of infants in the iNO and control group with the condition.⁶⁷ No study specifically documented right heart failure (Appendix E, Evidence Table 8).

Methemoglobinemia. Twelve RCTs measured methemoglobin levels, and some measured nitrogen dioxide levels in administered gas.^{34, 37, 39, 40, 58, 59, 62-67} Most reported that

methemoglobin levels in all infants were not elevated,^{34, 59, 66, 67} or were below 2.5 percent,⁶⁵ three percent,⁶⁴ or four percent.³⁹ The Van Meurs, 2005 RCT of infants born before 34 weeks gestation with BW 400 to 1500 g found two infants (1 percent) in each group who had methemoglobin levels above four percent.⁴⁰ One infant in the iNO group had a methemoglobin level of at least eight percent, and the nitrogen dioxide level was at or above 3 ppm in two percent, and at or above 5 ppm in one percent. The multicenter Kinsella, 2006 trial reported a transient mild elevation of methemoglobin level in two of 398 (0.05 percent) infants, but elevation was not defined.³⁷ Three infants treated with iNO in the Schreiber, 2003 RCT had elevation in methemoglobin level that never rose above seven percent, and nitrogen dioxide was never above 2 ppm.⁵⁸ The Field RCT allowed the highest maximum dose of iNO, up to 40 ppm, and as many as eight of 55 (14.5 percent) preterm infants had methemoglobin levels above two percent; only one infant (1.8 percent) had nitrogen dioxide above 2 ppm for 30 minutes⁶³ (Appendix E, Evidence Table 9).

Conclusion

Key Question 2 analyzed 14 RCTs of iNO in preterm infants on mechanical ventilation for evidence of toxicity or short term risks of iNO. None of the 14 RCTs reported statistically significant effects of iNO on rates of PDA, sepsis, NEC, treated ROP, pulmonary hemorrhage, or air leaks. No study reported toxic accumulations of methemoglobin. None of the 13 RCTs that reported head ultrasound evidence of brain injury reported a statistically significant increase with iNO treatment. Two large RCTs, with more than 100 subjects in each group, reported a statistically significant reduction of a composite brain injury variable (IVH with ventriculomegaly, IPH or PVL) in the iNO group compared with placebo gas controls.^{37, 58} These two RCTs raise the question as to whether iNO has neuroprotective effects. There was no statistically significant difference between the iNO and control groups in a meta-analysis that pooled data from five RCTs that reported rates of the composite brain injury variable (IVH with ventriculomegaly, IPH or PVL). There was also no statistically significant difference in our meta-analysis of four RCTs with data on rates of PVL. However, not only do the RCTs vary widely in study design, but there is also little uniformity among studies as to when head ultrasounds were performed, who interpreted them (locally at each center or at more uniformly at one site), categories reported, and criteria used for each category. These RCTs were generally powered for death and BPD, and not for short term risks or brain injury. There is insufficient evidence for assessing the effect of iNO on the preterm infant's brain. There is a need for RCTs that obtain neuroimaging before initiation of treatment and at regular prespecified intervals, provide for uniform interpretation of neuroimaging studies, carefully define categories of types of brain injury, and clearly report rates of each type, and composites of brain injury in terms of surviving infants. Because they are so vulnerable as they are rapidly maturing, the effects of any intervention on the brain should be studied in every RCT involving preterm infants. Key Question 3 reviews the evidence of effects of iNO on longer term neurodevelopmental, pulmonary, and other health outcomes.

Key Question 3: Are there effects of iNO therapy on long term pulmonary and/or neurodevelopmental outcomes among premature infants who receive respiratory support?

Major Findings

- There is insufficient evidence to determine whether iNO therapy in preterm infants who require respiratory support influences the incidence of cognitive, motor or sensory impairments, or neurodevelopmental disability.
- There is evidence suggesting that iNO therapy in preterm infants who require respiratory support may decrease the use of respiratory medications at one year of age.
- There is insufficient evidence to determine whether iNO therapy in preterm infants who require respiratory support impacts long term health outcomes such as lung growth and development, pulmonary morbidity, rehospitalization after NICU discharge, and growth.

Detailed Analysis

Nine articles representing six RCTs report long term followup of health and neurodevelopmental outcomes at one year corrected for degree of prematurity or later (see Table 6). Field, 2005 reported on some health and neurodevelopmental outcomes at one year corrected for degree of prematurity of the multicenter INNOVO RCT.⁶³ Mestan, 2005 reported neurodevelopmental outcomes and growth at two years of the infants enrolled in Schreiber, 2003, the largest single center RCT.⁵⁶ Hintz, 2007⁵⁸ reported on survival, CP, cognitive abilities and neurodevelopmental impairment (NDI) in 18 to 22 month old survivors enrolled in the NICHD RCT of infants born before 34 weeks gestation with birth weight below 1500 g.^{30, 40} Neurodevelopmental impairment at one year corrected for degree of prematurity is included in the Van Meurs, 2007 paper that reported results from the NICHD RCT on infants born before 34 weeks gestation with birth weight above 1500 g.³⁹ For surviving infants in Ballard, 2006, Walsh, 2010 reported on neurodevelopmental outcomes and growth at two years of age, corrected for degree of prematurity, and Hibbs, 2008 reported on pulmonary and health outcomes at one year.^{34, 44, 57} In a paper focused mostly on economic costs and resource utilization, Watson, 2009 reported on survival and some neurodevelopmental outcomes at one year of age, corrected for degree of prematurity, for infants enrolled in Kinsella, 2006.^{36, 37} Bennett, 2001 reported on 30 month survival for all study participants who were discharged from the NICU, and neurodevelopmental outcomes for 21 of the 22 children alive at 30 months, corrected for degree of prematurity.⁷⁶ Huddy, 2008 followed the group of infants in Field, 2005 up to four to five years, and reported on several health and neurodevelopment related outcomes; this is the longest followup for any of the RCTs³⁵ (Appendix E, Evidence Tables 3 and 4; Table 6).

Trials that reported comparable neurodevelopmental outcomes were included in meta-analyses. There was some variability in the incidence of outcomes among the few trials that reported conditions such as CP, vision, and hearing impairment. The variability is likely due to the low prevalence of these conditions and small samples, as studies were not powered to detect difference in these outcomes. Few trials reported other long term health outcomes in a consistent manner, making pooled estimates of risk impossible, with the exception of pulmonary outcomes.

Table 6. Summary of outcomes for RCTs addressing KQ3

Outcomes	Number of studies	Total Sample size
Death and Survival	6 ^{30, 35, 36, 39, 44, 56, 57, 63, 76}	2635
Cerebral palsy	7 ^{30, 35, 38, 39, 56, 57, 76}	914
Cognitive outcomes	5 ^{30, 35, 39, 56, 57}	896
Sensory impairment	7 ^{30, 35, 36, 39, 56, 57, 63, 76}	951
NDI	7 ^{39, 30, 35, 36, 56, 57, 76}	1312
Death or NDI	4 ^{30, 36, 39, 76}	1236
Seizures	2 ^{35, 63}	81
Growth	6 ^{30, 35, 56, 57, 63, 72}	978
Oral feeding	1 ⁶³	43
Pulmonary and other health outcomes	6 ^{35, 36, 44, 63, 71, 72}	1344

Death and survival beyond the NICU. Followup studies of two RCTs reported survival into early childhood. Huddy, 2008³⁵ followed children from Field, 2005⁶³ until four to five years of age. A total of 108 infants were enrolled in the RCT, 44 survived to their first birthday. Overall survival to four to five years was 44 percent in the iNO group and 36 percent in controls. Mestan, 2005⁵⁶ reported that 85 percent of the iNO group and 77 percent of placebo controls from Schreiber, 2003⁵⁸ were alive at two years. Additionally, seven followup studies reported long term mortality rates for six RCTs. Study results are displayed in Table 7. None of the studies revealed a significant difference in mortality when comparing infants treated with iNO to controls. (Appendix E, Evidence Table 10).

Table 7. Studies addressing death and/or survival beyond the NICU

Author, Year	Original Trial	Followup	Control, n/N (%)	iNO, n/N (%)
Walsh, 2010 ⁵⁷	Ballard, 2006 ³⁴	2 years	23/288 (8.9)	24/294 (9.0)
Watson, 2009 ³⁶	Kinsella, 2006 ³⁷	1 year	98/384 (25.5)	80/385 (20.8)
Huddy, 2008 ³⁵	Field, 2005 ⁶³	4-5 years		
Hibbs, 2007 ⁴⁴	Ballard, 2006 ³⁴	1 year	2/230 (0.87)	2/225 (0.89)
Van Meurs, 2007 ³⁹		18 – 22 months	4/15 (26.7)	5/14 (35.7)
Hintz, 2007 ³⁰	Van Meurs, 2005 ⁴⁰	18 – 22 months	98/210 (47)	109/210 (52)
Mestan, 2005 ⁵⁶	Schreiber, 2003 ⁵⁸	2 years	23/102 (22.5)	16/105 (15.2)
Field, 2005 ⁶³		1 year	30/55 (54.5)	34/53 (64.2)
Bennett, 2001 ⁷⁶	Subheddar, 1997 ⁶⁴	30 months	10/22 (32)	7/20 (50)

A meta-analysis was conducted with all the trials that reported death at any time after NICU discharge, regardless of the age of the children at the time of the measurement. Two studies were excluded (Hibbs⁴⁴ and Huddy³⁵) because there was more than one followup study for the Ballard and Field trials. The pooled estimate shows no difference in mortality with iNO therapy compared to placebo, RR 1.02 (0.86, 1.20) (Figure 10).

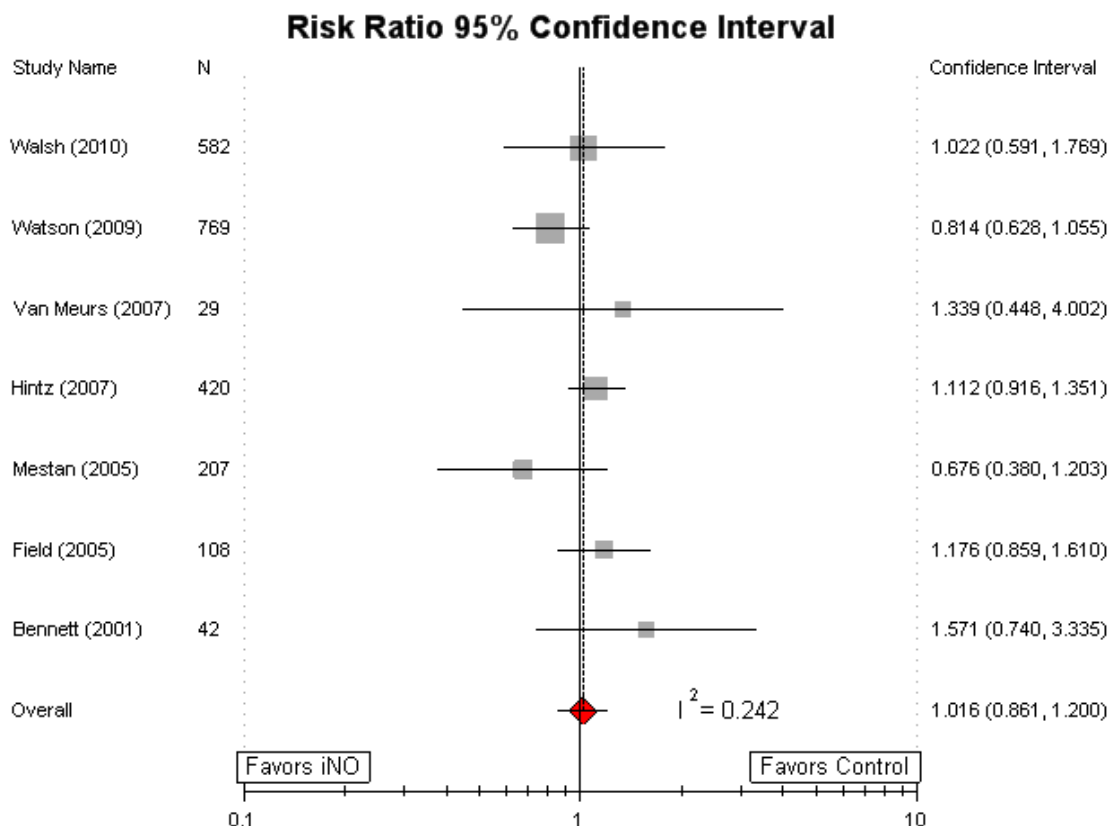

Figure 10. Meta-analysis of death at followup after NICU discharge

Cerebral palsy and motor outcomes. Cerebral palsy is a disorder of movement and posture caused by malformation or injury to the developing brain that cannot be diagnosed in the neonate, but requires a neurological examination and assessment of motor function at one or more years after birth. Cerebral palsy varies in terms of type (spasticity, extrapyramidal or mixed), anatomic distribution (diplegia, hemiplegia, etc.) severity, and associated disabilities (cognitive and/or sensory impairments). The more severe the CP, the earlier it can be diagnosed; diagnosis of mild CP is generally not made until two years or more. Diagnosis of CP requires a comprehensive neurodevelopmental examination focusing on abnormalities of muscle tone, deep tendon and other reflexes, movement and posture, as well as an assessment of motor function. The most common type of CP in preterm infants is spastic diplegia, which involves increased muscle tone and reflexes in both lower extremities with little or no involvement of the upper extremities. CP prevalence increases with decreasing gestational age and birth weight. Most studies reported moderate to severe CP. The functional classification for CP is included in the description of each study that reported this outcome.

The Hintz, 2007³⁰ 18 to 22 month followup study of Van Meurs, 2005⁴⁰ RCT of infants with birth weight 400 to 1500 g found CP in 20 percent of the iNO group and 11 percent of controls. CP functional impairment was defined as the ability to sit independently or with support but not ambulate independently (moderate CP), or the inability to sit or walk without support (severe CP). The initial RR was not significant at 1.85 (0.93, 3.71). When adjusted for birth weight, OI entry criterion strata, sex, BPD, IVH 3 or 4 or PVL, postnatal steroid exposure, study center, and

length of iNO exposure, the RR was significant at 2.41, indicating a higher rate of CP in iNO treated infants, but with a wide 95 percent confidence interval (1.01, 5.75) (Appendix E, Evidence Table 11).

Tanaka, 2007³⁸ evaluated a cohort of children at three years of age who had received iNO or 100 percent oxygen in the neonatal period for hypoxic respiratory failure with pulmonary hypertension. Cerebral palsy, defined as abnormal muscle tone in one extremity and abnormal control of movement and posture, was diagnosed in 12.5 percent of those treated with iNO compared to 46.7 percent who had been treated with 100 percent oxygen (p-value = 0.054) (Appendix E, Evidence Table 11). There was also a significantly lower odds of CP in children who had received iNO versus 100 percent oxygen (OR=0.16; 0.03, 0.98). This association persisted in several multivariate models.

The other five RCTs that evaluated for CP found no significant differences in the incidence of CP in the iNO group compared to controls. The Van Meurs, 2007 RCT of infants with birth weight above 1500 g found that none of the 17 infants who were followed to one year corrected for degree of prematurity developed CP.³⁹ In the Mestan, 2005 paper that reported two year outcomes of survivors of the Schreiber, 2003 RCT, CP rates were virtually the same, nine percent in the iNO group and 10 percent in controls.⁵⁶ They based their diagnoses of CP and its type on abnormalities in neuromotor tone, deep tendon reflexes, primitive reflexes, postural reactions, movement or coordination, and delay in motor milestones.⁵⁸ Walsh, 2010 reported similar findings from the Ballard, 2006 cohort: six percent of iNO treated infants and five percent of control infants developed CP by two years.^{34, 57} Motor functional impairment for CP was determined by Palisano's Gross Motor Function Classification Scale (at or above 2).⁸⁸ Of the seven infants in the iNO group of Subhedar, 1997 that were followed to 30 months none developed CP, compared to two of 14 controls (14 percent), who had significant abnormalities of tone or movement.^{64, 76} In the Huddy, 2008 report of four to five year outcomes of Field 2005, the CP rate (moderate to severe disability of motor function) was 13.6 percent in the iNO group and 12.5 percent in controls.^{35, 63}

A meta-analysis of the seven trials that evaluated motor outcome found no statistically significant difference in CP among infants treated with iNO compared with controls, RR 1.07 (0.67, 1.71) (Figure 11). A separate meta-analysis was performed with four trials that used the Bayley Scales Psychomotor Developmental Index below 70 to define motor delay.^{30, 39, 56, 76} Individually, none of these trials found a statistically significant difference in the incidence of motor delay when comparing those who had received iNO to controls. Similarly, the meta-analysis showed no statistically significant difference in the incidence of a motor delay with iNO therapy, compared with controls, RR 0.95 (0.66, 1.36) (Figure 11).

Figure 11. Meta-analysis of cerebral palsy

Cognitive outcomes. There were six RCTs and one cohort study that reported cognitive outcomes. The majority used the Bayley Scales of Infant Development Mental Developmental Index (MDI) for assessment and defined cognitive impairment as MDI < 70, two standard deviations below the mean. The only followup study to report a statistically significant difference in cognitive impairment between the iNO group and controls was the followup of Schreiber, 2003 reported by Mestan, 2005.^{56, 58} Their followup rate was 82 percent at two years corrected for degree of prematurity. They found that only 19 percent of the iNO group had a Bayley MDI score more than two standard deviations below the mean compared to 35 percent of controls, p-value = 0.03. This result must be considered in the context of the significantly lower rate of the combined variable of grade 3 IVH, IPH, and PVL in the iNO group compared to controls as reported in Schreiber, 2003 (Appendix E, Evidence Table 12).

Hintz, 2007 evaluated participants with birth weight 400 to 1500 g enrolled in Van Meurs, 2005 at 18 to 22 months of age. Forty-three percent of infants in the iNO group had MDI scores more than two standard deviations below the mean compared to 36 percent of controls, RR 1.2 (0.84, 1.73).³⁰ Infants in the Van Meurs, 2007 RCT with birth weight above 1500 g were followed to one year corrected for degree of prematurity. In the iNO group, 11 percent had MDI scores more than two standard deviations below the mean, compared to 25 percent of controls, RR 0.44 (0.50, 4.02).³⁹

A meta-analysis was performed using these three studies in which cognitive impairment was defined as MDI < 70. This revealed no statistically significantly difference between those treated

with iNO therapy and controls, RR 0.78 (0.39, 1.60) (Figure 12). As in the meta-analysis for the brain injury, there is substantial heterogeneity, reflecting that many of the same infants are included in this meta-analysis. Again, the Van Meurs, 2007³⁹ and Mestan, 2005⁵⁶ (followup of Schreiber, 2003) studies included infants with birth weight above 1500 g with a lower risk for brain injury and subsequent cognitive impairment than the Hintz³⁰ study (followup of Van Meurs, 2005) that restricted enrollment to those with birth weight of 400 to 1500 g.

In their two year followup of Ballard, 2006, Walsh, 2010 reported cognitive outcomes in terms of normal intelligence, defined as MDI score above 85, one standard deviation below the mean.^{34, 57} There was no significant difference in proportion of survivors with MDI above 85; there were 39 percent in the iNO group and 35 percent in the placebo control group. Translating these data into the proportion with cognitive delay, 61 percent in the iNO group and 65 percent in the placebo control group had MDI scores one standard deviation below the mean or lower. They also reported mean MDI scores for each group and found no significant difference: 81 +/- 20 versus 79 +/- 22 (Appendix E, Evidence Table 12). Bennett, 2001 reported the incidence of cognitive delay, defined as MDI < 85 in survivors from Subhedar, 1997 at 30 months of age corrected for prematurity.⁷⁶ There was no significant difference in the incidence of cognitive neurodevelopmental delay when comparing those treated with iNO to controls, RR 0.89 (0.37, 1.75).

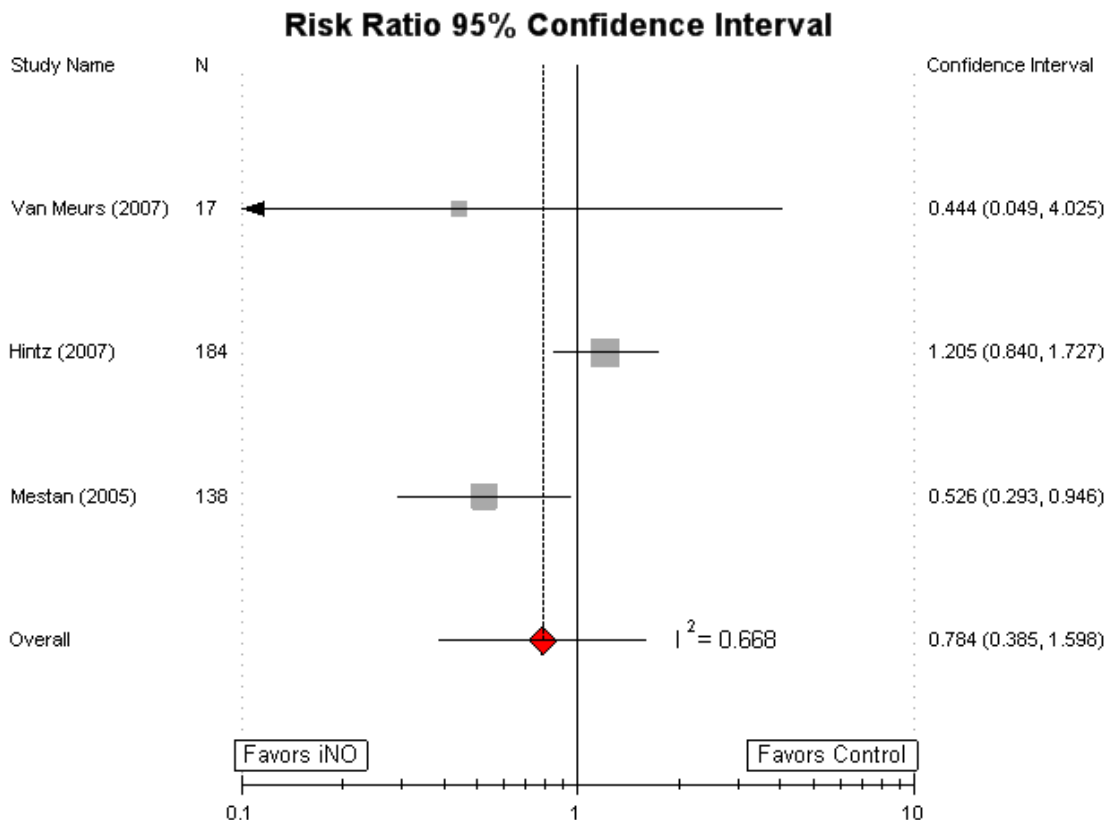

Figure 12. Meta-analysis of cognitive development as measured by the Bayley Scales Mental Developmental Index below 70

To evaluate cognition at four to five years, the Huddy, 2008³⁵ followup of the Field, 2005 cohort used the British Ability Scales (BAS),⁸⁹ which has norms similar to the Bayley and other intelligence tests, with a standardized mean of 100 and a standard deviation value of 15.³⁵ Three children in the iNO group and one control had severe impairments that precluded using the BAS. There were no statistically significant differences in mean General Conceptual Ability Score (GCAS) between the 19 children in the iNO group and the 15 children in the control group: 91.2 +/- 21.1 versus 81.3 +/- 22.5. They also found no statistically significant differences in the BAS cluster scores for verbal ability, pictorial reasoning, spatial abilities, and the nonverbal composite scores. There were six of 22 children (27 percent) in the iNO group with GCAS scores two or more standard deviations below the mean, compared with six of 16 controls (38 percent) (Appendix E, Evidence Table 12).

Sensory impairment. There were no significant differences between the iNO and control groups in proportion of children with visual impairment or hearing impairment in seven studies (representing six original trials) that report these outcomes. Visual impairments occurred in zero to four percent of children in the iNO group compared to zero to four percent in controls in the six studies that reported this outcome.⁶³ Our meta-analysis that included trials reporting early childhood blindness revealed no significant difference between those treated with iNO therapy and controls, RR 1.09 (0.52, 2.30) (Figure 13). Hearing impairments occurred in zero to nine percent of children in the iNO group compared to zero to seven percent of controls in the same six followup studies^{30, 39, 56, 57, 63, 76} (Appendix E, Evidence Table 13). The pooled risk ratio for hearing loss also showed no significant difference with iNO therapy compared to controls, RR 1.50 (0.69, 3.27) (Figure 14).

Neurodevelopmental impairment. Seven studies reported the proportion of children with neurodevelopmental impairment (NDI), a combined variable that included cognitive, neuromotor, and sensory impairments. Children with moderate to severe CP were included, as were children with severe visual or hearing impairments. All studies defined “cognitive impairment” as two or more standard deviations below the mean score for the assessment tool that was used. Most studies also included children with Psychomotor Developmental Index scores two or more standard deviations below the mean from the Bayley Scales of Infant Development^{30, 36, 39, 56, 57, 76} (Appendix E, Evidence Table 14, Table 8).

Figure 13. Meta-analysis of visual impairment

Figure 14. Meta-analysis of hearing impairment

Just as they found statistically significant differences in cognitive impairment, the Mestan, 2005 two year followup study of Schreiber, 2003 found that NDI rates were lower in the iNO group compared to placebo controls: 24 percent versus 46 percent, RR 0.53 (0.33, 0.87), p-value = 0.01. The six other followup studies revealed no significant differences between the two groups.^{35, 39, 56-58, 76} In two large RCT two year followup studies, as many as half of the survivors in both the iNO and control groups had NDI: 45 percent versus 49 percent respectively, RR 0.92 (0.75, 1.12) reported by Walsh, 2010 using Ballard, 2006 cohort; and 51 percent versus 47 percent respectively, RR 1.07 (0.8, 1.44) reported by Hintz, 2007 for the Van Meurs, 2005 multicenter RCT.^{57, 30} The Van Meurs, 2007 RCT of infants with birth weight above 1500 g reported a lower rate of NDI in both iNO and control groups, with no statistically significant difference between the two groups: 11 percent versus 25 percent, RR 0.44 (0.5, 4.02).^{30, 39} Despite the finding in Kinsella, 2006 of a lower rate of grade 3 IVH, IPH or PVL in infants in the iNO group, Watson, 2009 reported no statistically significant differences in the rate of NDI at one year corrected for degree of prematurity in infants in the iNO group compared to controls, 35 percent versus 34 percent.^{36, 37} Huddy, 2008 reported no significant differences in four to five year old children from the Field, 2005 cohort, with NDI in 36 percent of children in the iNO group and in 44 percent of controls.^{35, 63} Bennett, 2001 reported that for 30 month old children in the Subhedar, 1997 RCT, none of the seven survivors had NDI compared to 36 percent of controls^{64, 76} (Appendix E, Evidence Table 14).

Table 8. Studies addressing neurodevelopmental impairment

Author, Year	Age	Definition	Control, n/N (%)	iNO
Walsh, 2010 ⁵⁷	2 years	MDI or PDI<70, GMLS \geq 2, blind, deaf	115/234 (49)	109/243 (45)
Watson, 2009 ³⁶	1 year	CP, blind, severe HI, MDI or PDI<70	73/218 (33.5)	84/237 (35.4)
Huddy, 2008 ³⁵	4-5 years	Mod-Sev Disability	7/16 (44)	8/22 (36)
Hintz, 2007 ³⁰	18-22 months	MDI/PDI<70, mod-severe CP, VI	48/102 (47)	45/89 (51)
Van Meurs, 2007 ³⁹	18-22 months	MDI or PDI<70, mod-severe CP, blind, deaf	2/8 (25)	1/9 (11)
Mestan, 2005 ⁵⁶	2 years	CP, blind, HI, MDI<70	31/68 (46)	17/70 (24)
Bennett, 2001 ⁷⁶	30 months	MDI or PDI<70, CP, blind, HI	5/14 (36)	0/7 (0)

HI = hearing impairment; VI = visual impairment; GMLS = Palisano gross motor level score; MDI = mental development index; PDI = physical development index; CP = cerebral palsy

Our meta-analysis of trials that measured outcome at 12 to 30 months suggests no statistically significant difference in the proportion of infants with NDI between those given iNO versus the control group (RR 0.91 (0.77, 1.12)) (Figure 15).

Two followup studies reported the rate of children in each group who had no impairment. For the followup of infants from Kinsella, 2006, Watson, 2009 defined “no impairment” to include only those children who had MDI and Bayley Physical Developmental Index (PDI) above 85, and no CP or severe visual or hearing impairment.^{36, 37} They found no statistically significant differences in the proportion of children with no impairments at one year corrected for degree of prematurity between the iNO group and controls: 38 percent versus 37 percent. In reporting the 18 to 22 month followup results from Van Meurs, 2005 RCT on preterm infants with birth weight 400 to 1500 g, Hintz, 2007 used a similar definition of “unimpaired”: MDI and PDI \geq 85, no moderate to severe CP and not blind or deaf.³⁰ They found that 23 percent in the iNO group and 25 percent in placebo controls were unimpaired. The low proportion of survivors with no impairments is an indication of how sick the infants enrolled in the RCTs were. Conversely, there was a higher survival rate among infants with NDI. (Appendix E, Evidence Table 13).

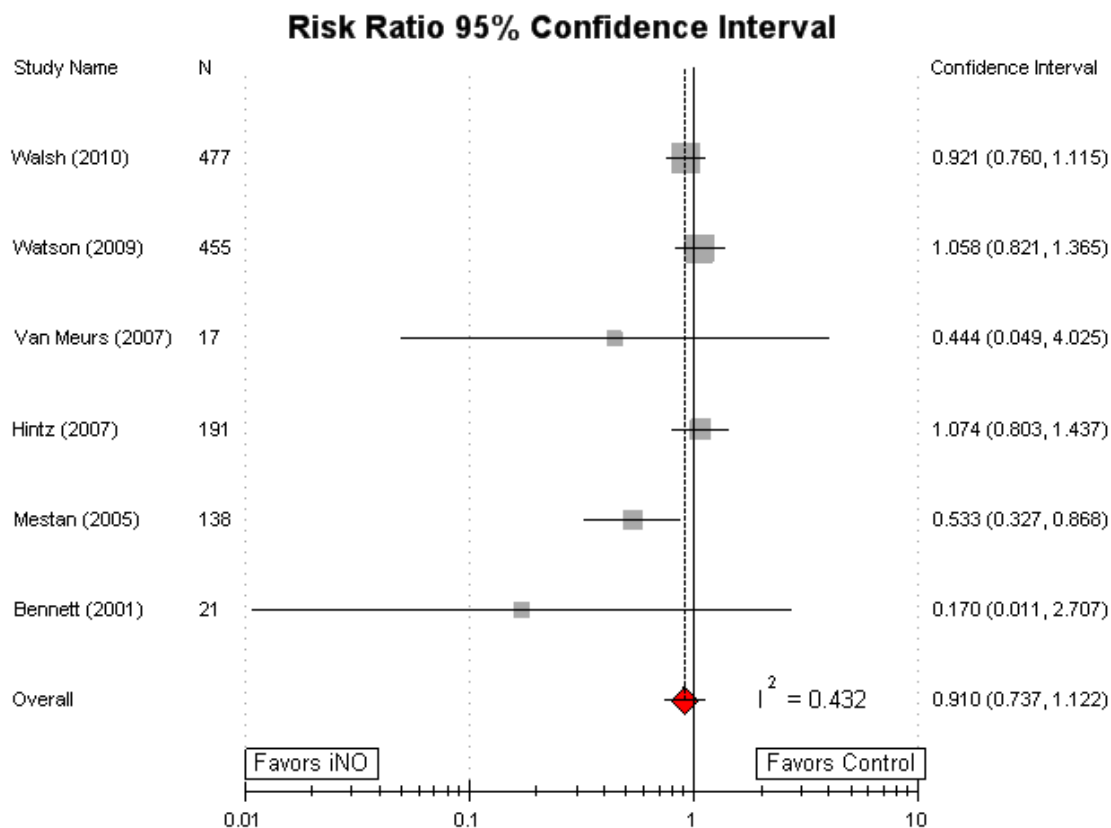

Figure 15. Meta-analysis of studies reporting NDI

Death or neurodevelopmental impairment. None of the four studies that reported the rate of the composite variable, death or NDI, for infants enrolled in four RCTs found any significant differences between the iNO and control groups.^{30, 36, 39, 76} Although Kinsella, 2006 reported lower rates of grade 3 IVH, IPH or PVL in infants in the iNO group compared to controls, Watson, 2009 reported no significant differences in the rate of death or NDI at one year corrected for degree of prematurity: 42.4 percent in the iNO group and 44.5 percent in placebo controls.³⁶ Similarly, in the two Van Meurs RCTs, there were no significant differences between the iNO groups and placebo controls; Hintz, 2007 reported that 78 percent of preterm infants with birth weight 400 to 1500 g in the iNO group died or had NDI compared to 73 percent of controls, RR 1.07 (0.95, 1.19)³⁰; while Van Meurs, 2007 reported that 43 percent of preterm infants with birth weight above 1500 g in the iNO group died or had NDI compared to 50 percent of placebo controls, RR 0.86 (0.37, 1.96).³⁹ In the Bennett, 2001 followup of Subhedhar, 1997, 63 percent in the iNO group and 59 percent in the control group died or had NDI at 30 months^{64, 76} (Appendix E, Evidence Table 14).

Long term health outcomes.

Seizures. Seizures can accompany complications that occur in the antenatal period or in the NICU, including perinatal asphyxia, hypoxia, hypoglycemia and other electrolyte abnormalities, intraventricular hemorrhage and meningitis. Seizures in premature infants that persist beyond the NICU are usually a result of brain injury and associated with other neurodevelopmental sequelae. Field, 2005⁶³ included “on anticonvulsants” and “fits in previous four weeks” with neuromotor outcomes at one year corrected age. These outcomes are based on available pediatrician

assessments. In the iNO group, three of the 25 infants, and one of the 18 control infants with available reports were being treated with anticonvulsants. Three infants in the iNO group and none of the 18 control infants had experienced a fit or seizure in the four weeks prior to the assessment. Seizures were included in the General Health domain of the four to five year assessments of infants enrolled in the Field, 2005 RCT performed by Huddy, 2008.³⁵ Children could be categorized as normal, impaired, or mildly, moderately, or severely disabled with regard to seizures. Of the five children who had seizures in the 12 months prior to assessment (3 of 22 iNO, 2 of 16 controls), three iNO and one control were on regular seizure medications, and considered to be impaired. One iNO child had more than one seizure per month and was classified as mildly disabled (Appendix E, Evidence Table 15).

Growth. There are five RCTs and one cohort study in which growth parameters were included with early childhood outcomes. Cheung, 1998 evaluated the 10 survivors from a cohort of 24 infants who received rescue iNO therapy for severe hypoxemic respiratory failure. One or more anthropometric measures (weight, length, head circumference) of four of the 10 (40 percent) infants evaluated at 13 to 40 months were below the third percentile on a standard growth curve when plotted at their corrected age.⁷² In the followup of survivors from the Van Meurs, 2005 RCT at 18 to 22 months,³⁰ Hintz, 2007 measured weight and head circumference. When comparing the infants who had received iNO to controls, there was no difference in the measures of weight and head circumference, or percentage of infants with weight or head circumference below the fifth percentile for corrected age, based on CDC growth charts⁹⁰ (Appendix E, Evidence Table 15).

Infants enrolled in the Field, 2005 trial had growth parameters reported at one year corrected age,⁶³ and four to five years chronologic age.³⁵ At one year, there were pediatrician reports on 25 infants who had received iNO, and 18 controls.⁶³ Infants were categorized by the number of standard deviations their length and weight were from a standardized height and weight.⁹¹ There was no reported analysis to determine whether this distribution was different between the two groups. The actual measure of head circumference was reported. The mean head circumference was similar in the two groups, within one standard deviation: iNO 45.5 cm (1.8), control 45.2 cm (1.6). In the followup study by Huddy, 2008, weight, length, and head circumference were measured in 22 participants from the iNO group and 15 controls at four to five year of age.³⁵ There were no differences in the standardized mean values⁹¹ for any of the three parameters between the iNO and control groups. It was noted that values were lower in both groups than those of normal population. Walsh, 2010⁵⁷ and Mestan, 2005⁵⁶ both evaluated infants at two years of age corrected for prematurity from Ballard 2006 multicenter RCT, and Schreiber 2003 single center RCT, respectively. In the former, there were no significant differences in measures of weight, length or head circumference. Mestan, 2005⁵⁶ reported the measures and generated z-scores using the CDC growth charts,⁹⁰ which revealed that both the iNO and control groups were smaller than the reference population for all measures. Unlike the others who reported growth measures, Mestan, 2005⁵⁶ found that those in the iNO group were significantly heavier than participants in the control group (median weights 11.7 kg versus 10.8 kg, p-value = 0.04; z-scores -0.49 versus -1.07, p-value = 0.02); and measures of length and head circumference were not different (Appendix E, Evidence Table 15). Participants lost to followup had a higher birth weight and greater gestational age at delivery, which could influence followup weight if they were not equally distributed among the iNO and control groups.

Oral feeding. Successful oral feeding requires the coordination of basic reflexes, more complicated motor skills, and effective breathing. Infants must coordinate these efficiently in

order to take in enough to support the energy expenditure required for this task, as well as growth. Any of the required skills can be adversely affected by premature birth and associated complications. Lung disease can increase the required energy expenditure that is necessary for maintenance and catch up growth. Only Field, 2005⁶³ reported oral feeding and did so as a secondary outcome measure. Reports from pediatricians revealed that three of 25 infants who received iNO had a stoma for feeding. Of these infants, only one was limited to feeding through the stoma only; two infants also took some pureed feeds orally. One infant who did not receive iNO (of 18) was limited to liquid feeds through a tube but did not have a surgical ostomy placed for feeding. Five iNO infants and four controls could only manage pureed foods. The remainder (17 iNO and 13 control infants) could also manage eating lumps (Appendix E, Evidence Table 15).

Pulmonary and other health outcomes. There were two cohort studies and four randomized controlled trials that reported pulmonary outcomes beyond NICU hospitalization. The reported markers of pulmonary health varied among studies and included the use of supplemental oxygen or respiratory medications, asthma or wheezing, respiratory disability, feeding tube, and recurrent aspiration.

The safety and efficacy study by Clark, 2002⁷¹ included infants ≤ 1250 grams birth weight, on mean airway pressure of ≥ 7 cm H₂O and FiO₂ ≥ 40 percent at 10 to 30 days of age. The focus of the study was safety and short term efficacy. However, records of 25 of the 29 survivors were available at six months of age and revealed that 10 of the infants continued to require supplemental oxygen (40 percent) (Appendix E, Evidence Table 15).

Cheung, 1998 reported on the ten survivors from the cohort of 24 infants who received iNO as rescue therapy for severe hypoxemic respiratory failure. Eight were diagnosed with bronchopulmonary dysplasia; all had supplemental oxygen discontinued by 10 months corrected age. Other pulmonary issues reported at followup that occurred in the range of 13 to 40 months corrected age include recurrent aspiration pneumonia (1/10), and chronic lung disease requiring bronchodilator therapy on a regular basis (1/10). Four of the 10 children had recurrent wheezing episodes and used bronchodilator therapy intermittently⁷² (Appendix E, Evidence Table 15).

Hibbs, 2007 reported the pulmonary outcomes at one year of 85 percent of the survivors enrolled in Ballard, 2006.^{34, 44} The control group had a greater prevalence of reported pulmonary morbidity at one year of age when compared to the iNO group, based on respiratory symptoms (56.4 percent versus 49.6 percent ; OR 0.70 (0.48–1.03)), use of diuretics (28.4 percent versus 18.6 percent; OR 0.54 (0.34, 0.85)), systemic (17.7 percent versus 11 percent; OR 0.56 (0.32, 0.97)), and inhaled steroids (32.4 percent versus 19.8 percent; OR 0.50 (0.32, 0.77)), inhaled bronchodilators (54.1 percent versus 40.1 percent; OR 0.53 (0.36, 0.78)), and supplemental oxygen (9.4 percent versus 3.0 percent; OR 0.30 (0.13, 0.73)) at time of followup. Similarly, a greater percentage of the control infants had received supplemental home oxygen at some time since NICU discharge when compared to infants who had received iNO (49.5 percent versus 38.4 percent; OR 0.65 (0.44, 0.95)). However, there was no difference between the two groups in the percent who were rehospitalized for respiratory complications, or for any reason (21.9 percent versus 22.6 percent; OR 1.03 (0.65, 1.62)) (Appendix E, Evidence Table 15).

Field, 2005⁶³ reported respiratory outcomes from assessments by pediatricians in the first year of life for 25 of 55 who had received iNO and 18 of 53 infants who had not. Three iNO infants required respiratory support day or night, and three required supplemental oxygen. Ten used bronchodilators since discharge, and five used steroids. Respiratory symptoms in the three months prior to assessment included coughing at night (8 infants) and wheezing day or night (13

infants). Nine iNO infants had respiratory signs and symptoms on exam by the pediatrician. Two control infants required respiratory support day or night, and one required supplemental oxygen. Seven had used bronchodilators since discharge and five had used steroids. Respiratory symptoms in the three months prior to assessment included coughing at night (5 infants) and wheezing day or night (11 infants). Four control infants had respiratory signs and symptoms on exam by the pediatrician (Appendix E, Evidence Table 15).

Watson, 2009³⁶ assessed the outcomes of premature infants with respiratory failure who were randomized to receive iNO versus standard therapy. One year outcomes for these infants focused on health resource utilization and neurodevelopment. Use of supplemental oxygen at home was not a primary outcome variable but was reported as: 1) percentage of infants using supplemental oxygen prior to one year corrected age; 2) percentage on oxygen at one year of age; 3) duration of supplemental home oxygen. There were no significant differences in any of these measures by study arm when the entire group was evaluated. However, when stratified into birth weight categories, the smallest infants (500 to 749 g) who did not receive iNO had an advantage; fewer required supplemental oxygen at one year corrected age (4 percent versus 11.7 percent, p -value < 0.04).

Our meta-analysis including the trials of Field, 2005 and Hibbs, 2007, showed a statistically significant lower risk for those receiving iNO therapy compared to controls in the need for bronchodilator, RR 0.75 (0.62, 0.91), and steroid therapy, RR 0.62 (0.46, 0.85), but not in wheezing, RR 1.14 (0.56, 2.32).

Respiratory health was one of the domains assessed at four to five year followup by Huddy, 2008.³⁵ Twenty of 22 iNO infants and 15 of 16 control infants were reported to have no respiratory disability. The remaining infants in each group (2 iNO, 1 control) had mild respiratory disability (Appendix E, Evidence Table 15).

Conclusion

Our search identified twelve articles that included outcomes into early childhood. Six randomized controlled trials provided the baseline population for nine followup studies. Only Field, 2005 includes any post NICU followup among primary outcome measures, and this study included just over half of the planned sample size for this outcome. We also identified three cohort studies addressing long term outcomes. The two prospective cohort studies do not include controls for comparison. The controls in the retrospective cohort study are chosen from an earlier time period when practice standards other than just iNO use may have differed. Therefore, evidence to definitively answer any facet of this key question is not adequate.

Few individual studies and none of the meta-analyses revealed a significant association between neonatal iNO exposure and any neurodevelopmental outcome up to five years of age. For CP the two studies that did show associations conflicted in the direction of association. Tanaka, 2007 reports a decreased incidence of CP in the iNO group and Hintz reports an increase in CP in the iNO group. Both studies also had design or statistics issues that limit interpretation of the results. Mestan, 2005 reported a lower incidence of MDI < 70, NDI and the composite variable, death or NDI in those treated with iNO from Schreiber, 2003. This provides consistency, as the latter found a lower rate of CLD or death, and significant perinatal brain injury in the iNO treated infants. Of the studies that report growth parameters, Mestan, 2005 also reported the only difference in any anthropometric measure; the iNO treated infants were heavier at the time of followup. This set of results provides an incentive to pursue additional randomized

controlled trials of iNO in premature infants with primary outcomes, such as neurodevelopment, that extend into early childhood.

Of the studies that reported pulmonary outcomes after NICU discharge, only Hibbs, 2008⁴⁴ found significant associations that favor iNO use in the NICU; iNO treated infants from Ballard, 2006 were less likely to use bronchodilators and steroids at one year of age corrected for prematurity than controls. Field, 2005 provided the only other comparable data for meta-analyses. This study increased total sample in the meta-analyses by only 10 percent and the addition of this study to the meta-analysis did not have any significant influence on the results. Meta-analyses found statistically significantly lower use of bronchodilators and steroids in the iNO treated infants at followup. Ballard, 2006 treated infants with iNO or study gas at a later chronological age than most RCTs (at 7 to 21 days) and for the longest duration, a minimum of 24 days. This is compelling evidence, but it is not sufficient to recommend routine use of iNO for protection against chronic respiratory illnesses of childhood. It does, however, warrant directing focus to additional RCTs of iNO use in premature infants in the NICU and considering that the timing of initiation and duration of therapy may play an important role in outcome. Design of future studies should focus on early childhood outcomes, with definitive and objective outcome measures.

Key Question 4. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary across subpopulations of premature infants?

Major Findings

- There is insufficient evidence to determine whether the effect of iNO therapy on mortality, BPD, or motor impairment differs by the birth weight of the treated infants.
- There is insufficient evidence to evaluate the relationship between iNO therapy and infant sex, race/ethnic group, gestational age, or socioeconomic status.
- There are no published data available to evaluate the association between iNO therapy and, antenatal steroids, chorioamnionitis, multiple birth, or growth restriction.
- There is insufficient evidence concerning the relationship between iNO therapy and the severity of illness.
- There is insufficient evidence that iNO therapy improves outcome of infants suffering respiratory failure from pulmonary hypoplasia, respiratory distress syndrome or pulmonary hypertension.
- There is no consistent pattern of infants that respond to iNO therapy and those that do not.

Detailed Analysis

Six randomized controlled trials,^{34, 37, 40, 58, 63, 62} four with long term followup,^{30, 36, 56, 57} and seven other studies^{38, 68, 69, 70, 73, 74, 77} addressed one or more subpopulations of interest in this Key Question (Table 9).

Four RCTs investigated whether iNO therapy has a differential effect by birth weight^{37, 40, 58, 34}; three of the trials^{34, 37, 40} reported long term followup.^{30, 36, 57} Birth weight subgroup analyses

were planned *a priori* in two trials^{34, 37, 58} and were done post hoc for the other two trials.^{40, 58} Three trials enrolled infants at \leq three days of age,^{40, 58, 92} while the fourth RCT enrolled infants at seven to 21 days of age.³⁴

Only small numbers of trials have addressed the effect of iNO therapy on other subpopulations including the severity of infant illness, as measured by the oxygenation index (OI)^{40, 58, 63} or respiratory severity score,³⁴ race,^{34, 37, 57, 62} sex,^{34, 57, 62} gestational age,⁶² pulmonary hypertension,³⁸ and pulmonary hypoplasia.^{69, 77}

Descriptions of studies that evaluate iNO therapy in subgroups of infants by demographic characteristics are reviewed first below. Studies that evaluated iNO therapy by severity of illness indicators and causes for respiratory failure follow (Appendix E, Evidence Tables 3 and 4; Table 9).

Birth weight. The evidence for the effect of iNO is presented in standard birth weight groupings: < 750 g, 750 to 999 g, 1000 to 1250 g, \leq 1000 g, > 1000 g, and others. For individual studies, the birth weight stratum may vary slightly from the category heading. For instance, results for a study using the stratum \leq 750 g are included under the heading < 750 g. Ballard, 2006³⁴ is an exception as infants were categorized into birth weight groups of 500 to 799 g and 800 to 1250 g. This trial has been reviewed in the birth weight category of < 750 grams and 1000 to 1250 grams birth weight

Birth weight < 750 g. In two trials,^{30, 71} including one with 384 infants with birth weight between 500 g and 749 g, there was no difference in mortality in the NICU,³⁷ or survival without chronic lung disease⁵⁸ between those treated with iNO and controls. In followup to a third trial,⁴⁰ mortality at 18 to 22 months was significantly higher in the iNO group compared with the controls (73 percent versus 56 percent; p-value = 0.01).³⁰ A fourth trial, Ballard 2006³⁴, reported no significant difference between infants treated with iNO and controls in survival without CLD at 36 wks PMA (RR 1.26 (0.98, 1.62)) or death (RR 1.02 (0.96, 1.08)), among infants with birth weight of 500 to 799 g⁸⁰ (Appendix E, Evidence Table 16).

No difference was reported in the incidence of BPD at 36 weeks PMA between groups for the three trials that reported the outcome.^{34, 37, 40} At one year corrected age, Watson 2009³⁶ reported more infants treated with iNO in Kinsella, 2006³⁷ remained on oxygen compared with control infants (11.7 percent versus 4 percent, p-value = 0.04). (Appendix E, Evidence Tables 16).

Table 9. Summary of outcomes for RCTs addressing KQ4

Subanalysis	Outcome	Number of Studies	Total sample size
Birth weight < 750 g	Death	3 ³⁰	573
	BPD at 36 weeks PMA	5 ^{34, 36, 37, 40, 44}	1464
	Death or BPD	4 ^{37, 34, 36, 58}	1355
	Survival without BPD	2 ^{34, 58}	601
	NDI	2 ^{30, 36}	254
	Death or NDI	1 ³⁰	94
Birth weight 750-999 g	Death	2 ^{37, 40}	388
	BPD at 36 weeks PMA	1 ^{37, 40}	380
	Death or BPD	2 ^{36, 37, 40}	865
	Survival without BPD	1 ⁵⁸	57
	NDI	2 ^{36, 37, 40}	384
	Death or NDI	1 ³⁶	273
Birth weight <1000 g	Death	1 ^{30, 40}	316
	BPD at 36 weeks PMA	1 ⁴⁰	155
	Death or BPD	1 ⁴⁰	316
Birth weight 1000-1250 g	Death	1 ^{36, 37}	129
	BPD at 36 weeks PMA	1 ³⁷	129
	Death or BPD	2 ^{36, 37}	251
	NDI	1 ³⁶	77
Other Birth weight categories	Death	3 ^{34, 58, 740, 30}	343
	BPD at 36 weeks PMA	3 ^{34, 58, 740†}	343
	Death or BPD	1 ^{40‡}	104
	Survival without BPD	2 ^{34, 58‡}	239
	Survival with BPD	2 ^{34, 58‡}	239
Gestational age	Survival without BPD	1 ⁶²	795
Sex	Survival without BPD	1 ⁶²	795
Race	Survival without BPD	1 ³⁴	582
	Death, ICH, and PVL	1 ³⁷	793
Socioeconomic status	NDI	1 ⁵⁷	396
OI	Risk of Death	1 ^{40, 63}	108
	BPD and Death or BPD	3 ^{40, 58, 63}	726
	NDI	1 ⁵⁶	138
	Death or disability	1 ⁶³	108
Respiratory severity score	Survival w/o BPD	1 ³⁴	582
	NDI	1 ⁵⁷	477
RDS	BPD at 36 weeks PMA	1 ⁶³	108
	Death or NDI	1 ⁶³	108
Pulmonary hypoplasia	Death	2 ^{69, 77}	30
	BPD at 36 weeks PMA	2 ^{69, 77}	25
	Death or BPD	1 ⁷⁷	12
	NDI	1 ⁷⁷	4
Pulmonary HTN	Cerebral Palsy	1 ³⁸	31
Responders vs. nonresponders	Death	3 ^{68, 70, 73, 74}	169
	BPD, ventilator dependant survivors	1 ^{70, 74}	105
	Survival to discharge	1 ⁷³	41

* Birth weight 500-799g

† Birth weight 1000-1500g

‡ Birth weight >1000g

§ Birth weight 800-1250g

BPD = Bronchopulmonary Dysplasia; PMA = Post menstrual age; NDI = Neurodevelopmental impairment; IVH = Intraventricular hemorrhage; ICH: Intracranial Hemorrhage; PVL = Periventricular leukomalacia; CP = Cerebral palsy

No meta-analyses were conducted for this Key Question because of the differences in the definitions of subgroups across studies and the reported outcomes measured.

Similar rates of the composite outcome death or BPD at 36 weeks PMA were reported for iNO treated infants and controls in all three studies that reported this outcome.^{34, 37, 58} In one followup study, the combined outcome of death or an oxygen requirement to one year of age occurred in 37 percent of infants in each group³⁶ (Appendix E, Evidence Tables 16).

Inhaled nitric oxide therapy did not improve neurodevelopmental outcome in this birth weight category. Neurodevelopmental impairment (NDI) was similar between iNO treated infants and controls when measured by Hintz 2007 at 18 to 22 months corrected age (NDI defined as including any of the following: moderate to severe CP, blind, deaf, MDI < 70, or PDI < 70),³⁶ by Walsh, 2010 at 24 months corrected age (NDI defined as moderate or severe CP, bilateral blindness, bilateral hearing loss requiring amplification, or score <70 on the Bayley Scales MDI or PDI) (RR 0.85 (0.67, 1.08))⁵⁷, and by Watson 2009 at one year of age corrected for gestational age at birth (NDI defined as including any of CP, blindness, severe hearing loss, MDI < 70 or PDI < 70).³⁰ In two followup studies^{30, 36} the composite outcome death or NDI was similar between the groups. The composite death or moderate to severe CP occurred more frequently in the iNO treated infants than controls (81 percent versus 62 percent, p-value = 0.0039), in one study.³⁰ (Appendix E, Evidence Table 16).

Birth weight 750 to 999 g. No differences were reported between iNO and control infants in this subgroup with respect to mortality, BPD, the combined outcome of death or BPD, neurodevelopmental impairment (NDI),^{37, 40} or survival without BPD⁵⁸ in the three studies. Watson, 2009 reported that iNO treated infants had lower rates of death or NDI at one year compared with controls (32.1 percent versus 44.4 percent, p-value=0.04), as well as a decreased rate of the combined outcome of death, on oxygen, or NDI at one year corrected age (32.9 percent versus 45.1 percent, p-value = 0.04)³⁶ (Appendix E, Evidence Table 16).

Birth weight <1000 g. Only one study examined this birth weight subgroup, using post hoc analyses. The iNO treated infants had a higher mortality rate than the control group (62 percent versus 48 percent, RR 1.28 (1.06, 1.54)), but they also had a higher rate of severe (Grade 3 or 4) IVH (43 percent versus 33 percent, RR 1.40 (1.03, 1.88)). No difference was found in the incidence of BPD, or the composite outcome death or BPD⁴⁰ (Appendix E, Evidence Table 16).

At followup to 18 to 22 months corrected age, the iNO group had a higher rate of death (98/152, 64 percent) than the control group (79/152, 52 percent; p-value=0.04). Those treated with iNO also had a 22 percent greater rate of death or moderate to severe CP at 74 percent (111/151) compared to 59 percent (89/152) in the control group (RR 1.22 (1.05, 1.43) p-value = 0.01)³⁰ (Appendix E, Evidence Table 16).

Birth weight 1000 to 1250 g. The largest RCT that described birth weight subgroups and outcomes is Kinsella, 2006.³⁷ For this higher birth weight stratum, Kinsella reported a significant reduction in the combined outcome of death or BPD for the iNO treated infants (38.5 percent versus 64.1 percent, RR 0.60 (0.42, 0.86)), as well as a lower rate of BPD alone (29.8 percent versus 59.6 percent, RR 0.50 (0.32, 0.79)), although there was no difference in death alone. In followup at one year corrected age, there were no significant differences in the incidence of NDI, death, subjects on oxygen, or any composite outcomes³⁶ (Appendix E, Evidence Table 16).

In the Ballard, 2006 RCT,³⁴ which stratified infants across the wider birth weight category of 800 to 1250 g, there was no significant difference for iNO treated infants compared with controls for death (RR 1.00 (0.95, 1.06)) or survival without BPD at 36 wks PMA (RR 1.25 (0.88, 1.79)).⁸⁰ There was also no significant difference between iNO treated infants and controls for

BPD alone (51.5 percent versus 61.5percent) nor death or survival with BPD (54.6 percent versus 64.8 percent).⁸⁰ In followup at two years corrected age,⁵⁷ there was no difference between groups in the incidence of NDI (RR 1.07 (0.76, 1.50)).

Other birth weight groups including infants larger than 1250 g. No differences were reported for any outcome in studies that reported birth weights of 1000 to 1500 g^{40, 58} or >1500 g.⁵⁸ However, in post hoc analyses for the subgroup of infants with birth weight > 1000g, Van Meurs, 2005⁴⁰ found a lower rate of the composite outcome of death or BPD for the iNO treated group compared to controls (50 percent versus 69 percent, p-value = 0.03; RR 0.72 (0.54, 0.96)), but no difference in death or BPD alone (Appendix E, Evidence Table 16).

We determined that meta-analyses of trials reporting outcomes by birth weight subgroups would not be performed due to the differences in definitions of birth weight categories, the marked variability in iNO administration and differences in outcomes reported in these few trials.

Gestational age. Mercier, 2010⁶² assessed the relationship between iNO and gestational age at birth in infants born at less than 29 weeks. A similar incidence in survival without BPD at 36 weeks PMA was reported for infants treated with iNO therapy and controls resulting in a risk ratio for those with gestational age <26 weeks of RR 1.14 (0.71, 1.82), and for those with gestational age ≥26 weeks of RR 0.94 (0.64, 1.38) (Appendix E, Evidence Table 16).

Sex. Two RCTs commented on the association of iNO therapy and an infant's sex. In post hoc analysis, Ballard, 2006³⁴ stated that there was no difference in the response to iNO according to sex, but no data were shown. In the two year followup to Ballard, 2006, Walsh, 2010 reported there was no interaction between treatment with iNO and infant sex for the composite outcome NDI.⁵⁷

Mercier, 2010⁶² also showed no treatment effect by sex with similar relative risks of survival without BPD at 36 weeks PMA among girls treated with iNO compared with controls, RR 1.18 (0.76, 1.83), and boys treated with iNO compared with controls, RR 0.85 (0.58, 1.26) (Appendix E, Evidence Table 16).

Race/ethnicity. Kinsella, 2006³⁷ performed post hoc analyses and found no significant effect of race or ethnic group on the composite outcome of death, ICH or PVL following iNO treatment. In a post hoc analysis by Ballard, 2006³⁴ the effect of iNO did not differ significantly according to race or ethnicity (p-value = 0.06).⁷⁵ The risk ratios for survival without BPD at 36 weeks PMA by individual race follow: whites RR 1.06 (0.76, 1.47), blacks RR 1.72 (1.20, 2.47), Hispanics RR 1.66 (1.06, 2.59), and other 0.54 (0.25, 1.14).⁸⁰ Walsh 2010, in two year followup to the Ballard, 2006 trial, found no significant interaction between iNO treatment and race, white infants versus non-white infants, in NDI.⁵⁷ Mercier 2010⁶² reported no difference between those receiving iNO and controls in survival without BPD for black infants, RR 1.49 (0.61, 3.65), or non-black infants, RR 0.94 (0.69, 1.28). (Appendix E, Evidence Table 16). None of the studies reporting on race/ethnicity were powered to address these subgroups.

Socioeconomic status. In the only study to consider socioeconomic indicators of outcome, Walsh, 2010 reported no statistically different risk of NDI at two year followup for infants treated with iNO and controls when mothers had less than a high school education, RR 0.77 (0.46, 1.30), compared to those that had a high school education or greater, RR 0.92 (0.72, 1.17)⁵⁷; no data was provided in the original trial³⁴ (Appendix E, Evidence Table 16).

Other subgroups. There were no trials that specified outcomes by subgroups of exposure to antenatal steroids, chorioamnionitis, multiple births, and small for gestational age.

Description of trials based on severity of illness.

Oxygenation index. Three RCTs used the oxygenation index (OI, OI = mean airway pressure in cm H₂O x fraction of inspired O₂ x 100)/postductal arterial partial pressure of O₂ (PaO₂) in mm Hg) as a surrogate measure of severity of illness.

The study of Van Meurs, 2005⁴⁰ required an OI \geq 10 on two consecutive arterial blood gases (ABGs) for study entry. Following the first interim analysis, due to a higher than expected mortality rate in both treatment and control arms, the respiratory criteria for study entry were revised to an OI \geq five followed by an OI \geq 7.5. In infants with birth weight 401 to 1500 g, the mean OI (SD) at randomization was 23 \pm 17 for the iNO treated infants and 22 \pm 17 for the controls. Post hoc analysis indicated no interaction between iNO treatment and OI stratum. The risk of death, BPD, and death or BPD were similar between the iNO treatment and control groups for those with a median OI \leq 17 and for those with OI > 17 at the time of randomization. Severe IVH or PVL rates were similar between groups within the OI strata⁴⁰ (Appendix E, Evidence Table 16).

Field, 2005 reported on a total cohort of 108 subjects with a notably high severity of illness as assessed by OI. At study entry, the iNO treated group had a median (IQR) OI of 32.9 (22.2, 49.8), and 55 percent had an OI > 30 as compared to the control group median OI 31.9 (17.4, 51.8), and 53 percent with an OI > 30. When primary outcomes were stratified by OI < 30 or \geq 30, there were no significant differences in death or severe disability (defined as no/minimal head control or inability to sit unsupported or no/minimal responses to visual stimuli) (RR 0.99 (0.76, 1.28), p-value = 0.62); death or supplemental O₂ at expected date of delivery (RR 0.83 (0.68, 1.02), p-value = 0.87); or death or supplemental O₂ at 36 weeks PMA (RR 0.98 (0.87, 1.12), p-value = 0.81) in the iNO group compared to controls⁶³ (Appendix E, Evidence Table 16).

In Schreiber, 2003,⁵⁸ a post hoc analysis was performed, stratified by OI as a measure of severity of illness. For the group of iNO treated infants with OI < 6.94 (median), there was a significantly decreased risk of the composite outcome death or survival with CLD compared with the placebo group (36 percent versus 67.4 percent; RR 0.53 (0.35, 0.81)). There was no significant difference for the subgroup with OI \geq 6.94. Mestan, 2009⁵⁶ reported the neurodevelopmental outcomes at a corrected age of two years for the cohort of survivors (N = 138). In a post hoc analysis, in comparison with the placebo group the iNO treated group with initial OI < 6.94 had no significant difference in abnormal neurodevelopmental outcome (defined as either disability (CP, bilateral blindness, or bilateral hearing loss) or delay (MDI < 70 or PDI < 70), RR 0.52 (0.26, 1.01), but for the iNO treated infants with initial OI \geq 6.94 there was 62 percent lower risk for abnormal neurodevelopmental outcome, RR 0.38 (0.16, 0.93) (Appendix E, Evidence Table 16).

We opted not to undertake a meta-analysis since these three RCTs had such a wide disparity in the OI criteria used, rendering them much less clinically comparable. The relatively low median OI in the Schreiber trial⁵⁸ reflects a population of infants presumably less critically ill than those in the Van Meurs trial⁴⁰ with a median OI of 17, and markedly less critically ill than those infants in the Field trial⁶³ with more than half having an OI > 30. The Mestan study is the only one to report neurodevelopmental outcomes by OI.

Respiratory severity score. In Ballard, 2006,³⁴ a simplified respiratory severity score was used, calculated as the mean airway pressure x FiO₂, since actual PaO₂ (needed to calculate the OI) was often not available. At study entry, the median severity score was 3.5 for both iNO treated and control groups, and was noted to be equivalent to an OI in the range of five to nine.

In post hoc analyses, there was no interaction between the severity score at study entry and treatment for the outcome survival without CLD at 36 weeks PMA.^{34, 80} Followup at two years corrected age showed no difference in NDI between iNO treated and control infants if the respiratory severity score was < 3.5, RR 0.93 (0.69, 1.26) or \geq 3.5, RR 0.93 (0.72, 1.19)⁵⁷ (Appendix E, Evidence Table 16).

Other measures of severity of illness. We found no trials that studied the effect of iNO therapy by subgroups defined by oxygen requirement alone.

Description of trials based on causes of respiratory failure.

Respiratory distress syndrome. In Field, 2005, the primary outcome measures were stratified by principal diagnoses, defined as acute preterm lung disease (presenting immediately after birth and randomized at \leq 3 days of age), chronic preterm lung disease (presenting immediately after birth and randomized for continuing problems after 3 days of age), and other (developed lung disease after recovering from an initial respiratory problem). There were no differences between iNO treated infants and controls in death or supplemental O₂ at 36 weeks PMA, RR 0.98 (0.87, 1.11); death or supplemental O₂ at the expected date of delivery, RR 0.83 (0.68, 1.01); or death or severe disability, RR 0.99 (0.76, 1.28)⁶³ (Appendix E, Evidence Table 16).

Pulmonary hypoplasia. In very low birth weight preterm infants, pulmonary hypoplasia can occur following maternal preterm premature rupture of membranes (PPROM) > five days with subsequent oligohydramnios, and may further be complicated by persistent pulmonary hypertension. Two groups of investigators conducted retrospective analyses of infants with suspected pulmonary hypoplasia. In a subset analysis of infants with suspected pulmonary hypoplasia from the two Van Meurs trials, Chock, 2009⁷⁷ compared six infants exposed to iNO with six controls; the infants were similar at baseline. There was no statistically significant difference between iNO treated infants and controls in death (33 percent versus 67 percent, p-value = 0.57), BPD at 36 weeks PMA in the seven survivors (2/5 (40 percent) versus 2/2 (100 percent), p-value = 0.43), or death or BPD (50 percent versus 100 percent, RR 0.50 (0.22, 1.11)). At 18 to 22 months followup, none of the four surviving iNO treated infants assessed had NDI (defined as moderate to severe CP, blindness, or deafness); the two survivors from the placebo group were lost to followup, and thus no comparisons were made. Uga, 2004⁶⁹ compared eight infants treated with iNO to 10 controls. All eight infants treated with iNO survived to 28 days compared to 5/10 control infants (p-value < 0.05). The groups had similar rates of BPD (undefined) (Appendix E, Evidence Table 16).

A meta-analysis was not performed for these two retrospective cohort studies with very limited numbers of infants enrolled, and widely different time points for death, i.e., prior to discharge home or within 365 days in hospitalized infants⁷⁷ versus seven and 28 days.⁶⁹

Pulmonary hypertension. In persistent pulmonary hypertension of the newborn (PPHN), the pulmonary vascular resistance remains elevated in the newborn period, and it is the primary U.S. FDA approved indication for iNO in the term and near term infant population. In a retrospective case control study of 31 singleton preterm infants at median 25 weeks gestational age (IQR 24 – 28 weeks) with clinical pulmonary hypertension confirmed by echocardiography, Tanaka, 2007 reported that at three years of age 2/9 (22.2 percent) infants with CP had been treated with iNO compared to 14/22 (63.6 percent) infants without CP³⁸ (Appendix E, Evidence Table 16).

iNO responders compared to nonresponders. Four studies reported primary outcomes by the presence or absence of response to iNO therapy. Yadav, 1999 reported results from a retrospective study of iNO given to 41 preterm infants with a mean OI of 40 on maximal medical therapies. Response to an initial 10 ppm iNO was defined as a decrease in OI by \geq 10 at one hour

of treatment. The 26 responders and 15 nonresponders were similar with respect to birth weight, gestational age, and OI at the start of treatment. Death was reported as 11/26 (42 percent) for responders but 14/15 (93 percent) for nonresponders. In a multivariable model, early response to iNO was associated with survival to discharge (p-value = 0.01)⁷³ (Appendix E, Evidence Table 16).

Banks, 1999 studied iNO usage in severe BPD in 16 ventilator dependent preterm infants more than a month old (range 1 to 7 months). In this open label non controlled trial, iNO was administered at 20 ppm for the first 72 hours, then titrated slowly (median duration 27 days) for responders or discontinued in 24 hrs for nonresponders. Non response was defined as a 10 percent increase in oxygen requirement, a PaCO₂ of 70 mm Hg on baseline ventilator settings, worsening chest x ray, or a methemoglobin of > five percent within 72 hours of starting iNO therapy. Mortality for the overall cohort was 44 percent (7/16). For iNO responders, 4/11 (36 percent) died over the range of 11 days to five months, while in the nonresponder group 3/5 (60 percent) died and the two survivors remained ventilator dependent⁷⁰ (Appendix E, Evidence Table 16).

Kumar, 2007 performed a retrospective chart review of preterm infants < 37 weeks gestational age at birth with pulmonary hypertension treated with iNO. Pulmonary hypertension was diagnosed by echocardiography within the first four weeks of life; iNO treatment at doses of 5 to 15 ppm was at the discretion of the clinical team after an infant failed standard medical management. Within the gestational age range of interest in this evidence report, ≤ 34 weeks gestation, response to iNO was least likely to occur in the most immature infants: only 1/6 (16 percent) of infants < 29 weeks responded to iNO, defined as an increase in postductal PaO₂ of 20 mm Hg or greater within 30 minutes without any change in inspired oxygen, while 5/6 (83 percent) of infants 29 to 31 weeks gestation, and 5/6 (83 percent) of infants 32 to 34 weeks gestation responded to iNO⁶⁸ (Appendix E, Evidence Table 16). Mortality was significantly higher for the non responders (6/8, 75 percent) compared to iNO responders (4/15, 26 percent) (p < 0.04) (Appendix E, Evidence Table 16).

In a pilot study of the European iNO Registry, Dewhurst 2010,⁷⁴ reported the outcome for 44 preterm infants <34 weeks gestational age at birth. Infants with congenital heart disease were excluded. Infants were treated with a median starting dose of iNO of 20 ppm (range 3.3 to 25 ppm), and a median maintenance dose of 10 ppm (range 0.7 to 25 ppm). Response to iNO was defined as a 15 percent reduction in the baseline OI within 30 to 60 minutes of starting therapy; 26 infants responded and eight did not. Infants that responded to iNO were younger than non responders (median (IQR) gestational age at birth, 26 (25 to 29) weeks versus 29 (27 to 30) weeks, p-value = 0.043) and had a significantly higher baseline oxygen requirement (median (IQR) FiO₂ 1.0 (0.9, 1.0) responders versus 0.8 (0.5, 1.0) non responders; p-value = 0.021). Birth weight, age at starting iNO, starting dose, and baseline OI were similar between responders and non responders. There was no difference in mortality: 12 of the 21 responders for whom complete data were available died; 5/8 non responders died (Appendix E, Evidence Table 16).

No meta-analysis for the iNO responder versus non responder studies was undertaken due to the wide variations in iNO dosage and timing, as well as the variability and incomplete description of the diagnoses underlying the respiratory failure in these preterm cohorts.

Conclusions

For the question of whether iNO therapy has an effect on the major outcomes of interest (death and/or BPD or neurodevelopmental impairment) across various subpopulations of premature infants, we reviewed 17 studies which included six original RCTs,^{34, 37, 40, 58, 63, 74} with four followup studies,^{30, 36, 56, 57, 77} and seven other studies,^{38, 68, 69, 73, 70, 74, 77} As noted in the conclusion of Key Question 1, some of the studies that reported no significant differences in rates of death, BPD at 36 weeks PMA, or the composite outcome death or BPD at 36 weeks PMA for the overall cohort did find statistically significant subgroup differences. For example, two studies^{37, 40} report decreased rates of one or more of the major outcomes among infants with birth weight > 1000 grams.^{36, 56} The lack of consistency in defining or subdividing certain subgroups, (e.g., by birth weight, or oxygenation index) hampered the ability to answer this Key Question. In addition, many of the subgroup analyses performed were by post hoc analyses (e.g., birth weight, race), increasing the need for cautious interpretation of results. Some of the specific subpopulations of interest had little or no outcomes related data at all. Based on the current body of evidence, no definitive and generalizable conclusions may be made about iNO treatment in specific subpopulations. Future research is needed to examine the role of iNO treatment in these and alternative subgroups, so as to more clearly define populations of preterm infants which may benefit most from this therapy.

Key Question 5. Does the effect of iNO therapy on BPD and/or death or neurodevelopmental impairment vary by timing of initiation, mode of delivery, dose and duration, or concurrent therapies?

Major Findings

- There is insufficient evidence to determine if initiating iNO therapy for acute respiratory distress at \leq three days reduces the risk of death or bronchopulmonary dysplasia (BPD) at 36 weeks PMA, or death and neurodevelopmental disability at one year of age, corrected for gestational age at birth.
- In infants with developing BPD, there is insufficient evidence to determine if treatment with iNO during the second week after birth improves survival without BPD compared with treatment during the third week after birth.
- There is insufficient evidence to determine the effect of delivery of iNO by high frequency ventilation on either death or BPD, or neurodevelopmental outcome compared with conventional ventilation.
- There is insufficient evidence to support an optimal dose of iNO or duration of exposure to improve outcome or prevent harm.
- There is insufficient evidence to determine the effect of iNO with concurrent therapy.

Detailed Analysis

Fourteen RCTs reported in 21 papers addressed this key question. Two trials investigated the timing of the initiation of iNO therapy,^{34, 63} and two the mode of drug delivery, conventional or high frequency ventilation.^{40, 58} The dose of iNO varied considerably among the 14 studies. To examine the effect of dose on the primary outcomes, studies were categorized into those that administered iNO at only 5 ppm,^{37, 59, 62} those that delivered a maximum dose of 10 ppm,^{39, 40, 58, 61, 67} and those that gave 20 ppm or titrated the dose to the patients' response.^{34, 60, 63-66} Duration of iNO exposure also varied considerably among the 14 studies, from three to four days⁶⁴ to a minimum of 24 days.³⁴ As the majority of the studies administered iNO therapy until extubation, the evidence for the effect of duration of exposure of iNO on the primary outcomes of BPD and/or death or neurodevelopmental impairment could not be evaluated. Only two studies explicitly considered concurrent therapies, specifically systemic steroids, on the effect of iNO treatment.^{64, 76}

All trials reported death or survival, although the time of ascertainment of the outcomes varied across studies. If death or survival was reported at multiple endpoints in either the original study or in a long term followup publication (e.g., before NICU discharge, and at one year of age, corrected for gestational age at birth), the data are included in this evidence report. Seven of the randomized trials have reported long term followup.^{30, 35, 36, 56, 57, 76, 78} The followup studies have varying definitions of neurodevelopmental impairment (NDI), and use different measures of developmental progress, making direct comparison difficult. For questions concerning some subgroups (timing of initiation of iNO therapy, and mode of iNO delivery) the analyses are post hoc, therefore the results must be considered exploratory, as infants were neither randomly assigned to the subgroup, nor was the study powered to consider the variable (Appendix E, Evidence Tables 3 and 4; Table 10). The differences in treatment protocols in studies reporting on subgroups of infants may make pooled estimates of the effect of iNO therapy spurious, so meta-analyses were performed only with RCTs using similar dosing regimens.

Timing: Early versus late iNO administration. Two populations of preterm infants have been treated with iNO, those with early acute respiratory distress (immediately after birth), and those with evolving BPD. Early treatment generally begins within the first three days after birth in an effort to improve oxygenation in infants with acute hypoxemia, as in respiratory distress syndrome (RDS) or pneumonia. Late treatment may begin any time after three days, with evidence of progressive respiratory failure. Theoretically, late treatment avoids exposing an infant to iNO who would otherwise have resolving RDS during the first week. The goal of both strategies is to prevent the development of BPD and all its sequelae. Although the age at initiation of iNO therapy was available for all trials, aggregating studies into meaningful categories was problematic; RCTs started iNO therapy at < 48 hours, < 72 hours, < 96 hrs, four to 120 hours, < seven days, seven to 21 days, and < 28 days of age. Some trials also had varying additional entry criteria concerning severity of illness, further complicating the ability to combine studies into clinically meaningful groups. Because of this variability we did not conduct meta-analyses; instead we report the results of two RCTs that specifically considered the timing of the initiation of iNO therapy, both in post hoc analyses (Appendix E, Evidence Table 17).

Table 10. Summary of outcomes for RCTs addressing KQ5

Subanalysis	Outcome	Number of Studies	Total sample size
Timing: Early vs. late iNO administration	Death	1 ³⁴	582
	Death or BPD	1 ⁶³	108
	Death or Severe Disability	1 ⁶³	108
	Survival without BPD	1 ³⁴	582
Mode of drug delivery	Death	2 ^{30, 40}	838
	Death or BPD	1 ⁵⁸	207
	Death or CP	1 ³⁰	399
	Motor Developmental Impairment	1 ^{30, 58}	184
	NDI	2 ^{40, 58}	627
Dose of iNO, 5 ppm	Death	3 ^{37, 59, 62}	1666
	BPD at 36 weeks	3 ^{37, 59, 62}	1563
	Death or BPD	3 ^{37, 59, 62}	1661
	NDI	1 ³⁶	455
Dose of iNO, 10 ppm	Death	5 ^{39, 40, 58, 61, 67}	839
	BPD at 36 weeks	4 ^{39, 40, 56, 58, 67}	696
	Death or BPD	4 ^{39, 40, 58, 67}	694
Dose of iNO 20 ppm	Death	6 ^{34, 60, 63-66}	962
	BPD at 36 weeks	5 ^{34, 60, 63-65}	55
	Death or BPD	4 ^{34, 60, 63, 64}	774
	NDI	7 ^{30, 35, 56, 57, 63, 64, 76}	977
iNO with concurrent therapies	Death	2 ^{64, 76}	84
	BPD at 36 weeks	2 ^{64, 76}	84
	Death or BPD	2 ^{64, 76}	84

BPD = Bronchopulmonary dysplasia; iNO = Inhaled nitric oxide; NDI = Neurodevelopmental impairment; CP = Cerebral palsy

In a small sample, Field, 2005⁶³ found a similar risk of death or BPD at 36 weeks PMA in infants treated with iNO within three days of birth (25/38, 66 percent) and those treated at four to 28 days (12/17, 71 percent; RR 0.98 (0.87, 1.11)). There was an advantage to early iNO administration when death or BPD was measured at the expected date of delivery (61 percent versus 94 percent when iNO was initiated at 4 to 28 days), but the difference was attenuated after adjustment for diagnosis (acute lung disease beginning at birth and treated at \leq three days, chronic lung disease with respiratory distress at birth and continuing at four to 24 days; and other respiratory distress after recovery from an initial respiratory problem), and severity of illness (OI \leq 30 versus $>$ 30), RR 0.83 (0.69, 1.01). The time of initiation of iNO had no effect on death or severe disability, defined as no/minimal head control or the inability to sit unsupported or no/minimal response to visual stimuli, at one year of age corrected for gestational age at birth (RR 0.99 (0.76, 1.28)). No data were provided on the median time that iNO therapy was initiated in the early or late group, but the median (IQR) age of initiation for all infants receiving iNO therapy in the study was 1 (0, 6) days, making it unlikely that the groups were very different (Appendix E, Evidence Table 17).

In a large sample of nearly 600 infants with developing BPD, Ballard, 2006³⁴ reported a similar incidence of death at 36 weeks PMA between the iNO and placebo groups for those entering treatment at seven to 14 days (10.7 percent iNO versus 11.3 percent placebo), or those entering treatment at 15 to 21 days (6.6 percent iNO versus 5.8 percent placebo)³⁴ However, the likelihood of survival without BPD increased for infants beginning treatment at 7 to 14 days (RR 1.91 (1.31, 2.78)), a result that was not observed in those beginning treatment later, at 15 to 21

days (RR 0.99 (0.77, 1.28)).³⁴ This result may have been observed because of damage already done to the developing lung before late enrollment (Appendix E, Evidence Table 17).

In both of these studies analyses were conducted post hoc, so neither study was powered to find a statistically significant difference between the groups (Appendix E, Evidence Table 17).

Mode of drug delivery. Two randomized controlled trials, Van Meurs, 2005⁴⁰ and Schreiber, 2003⁵⁸ reported outcomes for infants treated with iNO and conventional mechanical ventilation compared with those treated with iNO and high frequency ventilation. Patients were randomly assigned to ventilation strategy in one trial,⁵⁸ but in the other, analyses were done post hoc.⁴⁰ Both studies reported neurodevelopmental followup to 18 to 24 months of age, corrected for gestational age at birth.^{30,56} Patients in the two trials differed by birth weight inclusion criteria (401 to 1500 grams,⁴⁰ ≤ 2000 grams⁵⁸) (Appendix E, Evidence Table 17).

Schreiber, 2003⁵⁸ found no difference in the combined outcome of death or BPD at 36 weeks PMA between infants randomized to treatment with iNO and conventional ventilation (RR 0.61 (0.41, 0.90)) compared with placebo and those randomized to iNO and high frequency ventilation (RR 0.92 (0.67, 1.26)) compared to placebo. Among survivors, the risk of abnormal neurodevelopmental outcome, defined as disability (CP, bilateral blindness, or bilateral hearing loss) or developmental delay (a score of <70 on the Bayley Scales of Infant Development II, but no disability) was not statistically different between high frequency ventilation and conventional ventilation, RR 0.92 (0.58, 1.46)⁵⁶ (Appendix E, Evidence Table 17).

In post hoc analysis, Van Meurs, 2005⁴⁰ reported that iNO delivered by conventional mechanical ventilation was associated with a 46 percent increase in the risk of death before discharge to home or within 365 days of birth among infants still hospitalized compared with placebo (RR 1.46 (1.10, 1.92)). The risk remained elevated at 18 to 22 months of age (RR 1.37 (1.05, 1.79)).³⁰ There was no increase in death, at either time, among infants treated with iNO delivered by high frequency ventilation compared to placebo. The risk of developing BPD at 36 weeks PMA was similar if iNO was delivered by conventional ventilation (RR 0.90 (0.65, 1.24)), or high frequency ventilation (RR 0.89 (0.72, 1.10)) (Appendix E, Evidence Table 17). Motor development was impaired at 18 to 22 months of age, in those treated with iNO and conventional ventilation (CP RR 1.29 (1.03, 1.60)), and there was an increased risk of death or moderate to severe CP (moderate CP was defined as the ability to sit independently or with support but cannot independently ambulate; severe CP was defined as unable to sit or walk even with support), RR 1.29 (1.03, 1.60)³⁰ (Appendix E, Evidence Table 17). The risk of disability, defined as moderate/severe CP, bilateral blindness, deafness, or MDI or PDI < 70 , was not affected by mode of iNO delivery, nor was the combined outcome of death or disability (high frequency ventilation RR 0.97 (0.70, 1.35); conventional ventilation RR 1.07 (0.64, 1.80)³⁰ (Appendix E, Evidence Table 17).

Although treatment with iNO and conventional ventilation was associated with some measures of adverse outcome, the estimates of harm are the result of post hoc analyses and so must be considered cautiously (Appendix E, Evidence Table 17). We did not perform a meta-analysis for mode of delivery as only one study prospectively randomized infants to conventional versus high frequency ventilation and the other generated comparisons by post hoc analyses.

No data are available on other methods of iNO delivery, such as high or low flow nasal cannula, or continuous positive airway pressure.

Dose of iNO. The initial dose of iNO varied from 5 ppm to 20 ppm among the 14 randomized trials. Data in preterm animal models of RDS indicates improvement in oxygenation in this range.⁹³ Fear of adverse side effects, specifically bleeding with resulting IVH, resulted in

limitation of iNO exposure in some studies (Appendix E, Evidence Table 17). For this review, studies were grouped as follows: dose restricted to 5 ppm; dose restricted to 10 ppm; dose titrated to response with a maximum of dose 20 ppm to 40 ppm, or dose given as 20 ppm. The effect of iNO doses on the primary outcomes are reviewed below. Meta-analyses were conducted with trials that reported death in the NICU at 36 weeks PMA or later; trials that reported death at seven days or 28 days were excluded. Separate meta-analyses were done that excluded Ballard 2006, because it was the only RCT that delivered iNO for a prolonged period of time (minimum 24 days); the results did not differ from what is reported.

Death. When the dose of iNO was restricted to 5 ppm there was no difference in death at 36 weeks PMA in two trials with 800 infants enrolled in each, RR 0.79 (0.61, 1.03)³⁷ and RR 1.34 (0.92, 1.95)⁶², or in death prior to hospital discharge, RR 0.90 (0.58, 1.40), in one trial with 80 infants⁵⁹ (Appendix E, Evidence Table 17). The pooled estimate of the risk of death showed no significant differences in treatment with this dose of iNO, RR 0.97 (0.70, 1.35) (Figure 16).

The risk of death was similar in infants that received iNO therapy at a maximum dose of 10 ppm compared with those receiving placebo in five randomized controlled trials^{39, 40, 58, 61, 67} (Appendix E, Evidence Table 17). In the two studies by Van Meurs the risk of death before discharge home or within 365 days for those still hospitalized was not improved with iNO therapy in infants weighing 401 to 1500 grams birth weight, RR 1.16 (0.96, 1.39),⁴⁰ or those with birth weight greater than 1500 grams, RR 1.34 (0.45, 4.00)³⁹ (Appendix E, Evidence Table 17). Three other studies found no significant decrease in death in the NICU (RR 0.68 (0.38, 1.20))⁵⁸; 20 percent iNO versus 30 percent placebo, p-value = 0.494⁶⁷, or at 28 days (41 percent iNO versus 31 percent placebo, no significant difference)⁶¹ (Appendix E, Evidence Table 17). Meta-analysis of the four studies that reported death in the NICU at 36 weeks PMA or later confirmed no statistically significant difference in death for infants treated with 10 ppm iNO compared to controls, RR 1.00 (0.73, 1.38) (Figure 16).

No study found a difference in death between infants that were treated with iNO at 20 ppm or iNO titrated to response and those given standard care, regardless of whether the outcome was measured at seven days,⁶⁶ during NICU hospitalization,^{60, 64, 65} at 36 weeks PMA,³⁴ 40 weeks PMA,³⁴ 44 weeks PMA,³⁴ at one year of age corrected for gestational age at birth⁶³, or four to five years of age³⁵ (Appendix E, Evidence Table 17). The pooled estimate of the relative risk of death at 36 weeks PMA or later during NICU hospitalization showed no statistically significant difference between infants given iNO therapy delivered at 20 ppm or titrated to response and controls, RR 0.91 (0.63, 1.30) (Figure 16).

The RR is similar across each dose category, with little heterogeneity, suggesting that the effect of iNO on the outcome of death does not vary by dose.

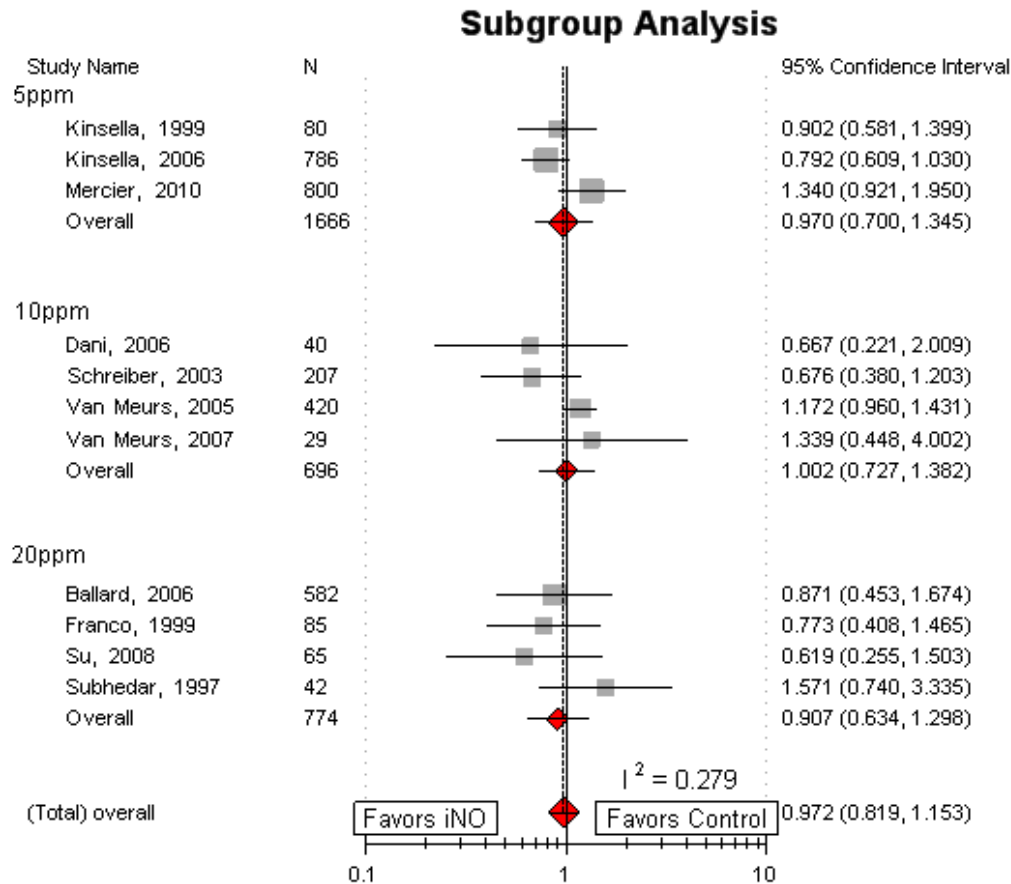

Figure 16. Meta-analysis for dose-stratified death, including only studies that reported death in the NICU at 36 weeks PMA or later

BPD at 36 weeks PMA. Bronchopulmonary dysplasia developed as frequently in those treated with 5ppm iNO as those treated with standard therapy when measured at 36 weeks PMA^{37, 59, 62} and when measured prior to hospital discharge⁵⁹ (Appendix E, Evidence Table 17) The pooled estimate of the risk of BPD for the three trials that reported the outcome at 36 weeks PMA was RR 0.94 (0.87, 1.02) (Figure 17).

The risk of BPD at 36 weeks PMA was mixed when iNO was given at a maximum dose of 10 ppm. The largest trial, conducted by Van Meurs 2005, with more than 420 infants, reported a 24 percent decrease in the risk of BPD compared to controls, RR 0.76 (0.58, 0.98).⁴⁰ Three other trials, with a combined enrollment of 276 infants, reported no significant difference between infants treated with iNO and controls^{39, 40, 58, 67} (Appendix E, Evidence Table 17). A meta-analysis with all four RCTs found a 25 percent reduction in the risk of BPD at 36 weeks for infants treated with iNO at 10 ppm compared to controls, RR 0.75 (0.61, 0.91) (Figure 17).

BPD at 36 weeks PMA was common, affecting one third to one half of all infants; the rate was not different between infants treated with 20 ppm or iNO titrated to response and those receiving standard care in the four RCT that used this dosing strategy.^{34, 63, 64, 65} The rate of BPD was also similar between the groups when defined as an oxygen requirement measured at 40

Figure 17: Meta-analysis for dose-stratified BPD at 36 weeks PMA

weeks PMA (22 percent iNO versus 29 percent placebo)³⁴, 44 weeks PMA (9 percent iNO versus 12 percent placebo),³⁴ and at one year, corrected for gestational age at birth (15 percent iNO versus 6 percent placebo)⁶⁰ (Appendix E, Evidence Table 17). A meta-analysis confirmed no significant difference in the risk of BPD at 36 weeks with iNO therapy at this dose, RR 1.00 (0.74, 1.34) (Figure 17).

Death or BPD. There was no reduction in the composite outcome of death or BPD with 5ppm iNO compared with controls, when measured at 36 weeks PMA,^{37, 62} or prior to hospital discharge⁵⁹ (Appendix E, Evidence Table 17). Meta-analysis with these three trials resulted in a RR 0.94 (0.88, 1.01) (Figure 18).

Evidence concerning the risk of death or BPD was mixed among the trials that gave 10 ppm iNO (Appendix E, Evidence Table 17). In the largest trial,⁴⁰ with more than 200 patients in each arm, the RR of death or BPD at 36 weeks PMA in the iNO group was 0.97 (0.88, 1.07). A similar lack of benefit was found in a small trial of infants with birth weight > 1500 g when death was measured before hospital discharge or at 365 days for infants still hospitalized (RR 0.83 (0.43 1.62)).³⁹ However, two other studies reported iNO was associated with a decreased risk of death or BPD at 36 weeks PMA. In Schreiber, 2003,⁵⁸ with more than 100 infants in each arm, the risk of death or BPD was decreased 23 percent in the iNO treated group (RR 0.77 (0.60, 0.98)), and in a small study with 20 infants in each group, Dani, 2006⁶⁷ reported an 89 percent decrease in risk (OR 0.11 (0.02, 0.61)) among the iNO treated group (Figure 18).

The opposite direction of the effect of iNO therapy at 10 ppm in the two largest trials may be accounted for by the degree of illness of infants at study entry. Infants in the study of Schreiber, 2003⁵⁸ had a substantially lower oxygenation index at study entry (OI median (IQR) 7.3 (4.1, 12.3) iNO group versus 6.8 (4.4, 12.7) control group) than infants in the study of Van Meurs, 2005⁴⁰ (OI mean (SD), 23 (17) iNO group versus 22 (17) placebo group) (see discussion of OI under Key Question 4) (Appendix E, Evidence Table 17). A meta-analysis revealed no significant difference in the risk of the combined outcome of death or BPD at 36 weeks PMA for infants treated with iNO at 10 ppm compared to controls, RR 0.81 (0.64, 1.03) (Figure 18).

In the four studies^{34, 60, 63, 64} that dosed iNO at 20 ppm or titrated to response, 50 percent to 100 percent of infants in each arm died or had BPD at 36 weeks PMA (Appendix E, Evidence Table 17). The pooled relative risk, RR 0.94 (0.84, 1.06), confirmed no difference to iNO treatment under these treatment protocols (Figure 18).

Neurodevelopmental impairment. In a followup study of Kinsella, 2006, Watson 2009³⁶ reported the rate of neurodevelopmental impairment (CP, severe hearing loss, blindness, or MDI or PDI < 70) at one year of age, corrected for gestational age at birth, was similar in the infants that received iNO at 5 ppm (35.4 percent) and those that received standard therapy (33.5 percent) groups (Appendix E, Evidence Table 17).

Figure 18: Meta-analysis for dose-stratified death or BPD.

Only two of the studies giving iNO at 10 ppm evaluated long term neurodevelopmental outcome and they found opposite effects.^{40, 58} Reporting the followup of Van Meurs, 2005, Hintz, 2007,³⁰ found no improvement in the combined outcome of death or neurodevelopmental impairment, defined as moderate to severe CP, blindness, deafness or an MDI or PDI < 70, at 18 to 22 months of age for infants treated with iNO compared to placebo, RR 1.07 (0.95, 1.19), or in death or moderate to severe CP, RR 1.17 (0.99, 1.38). Moderate to severe CP was increased in the iNO group (20 percent versus 11 percent), a difference that was not significant in univariate analysis, but reached significance in multivariable models after adjustment for infant characteristics at study entry in one model, RR 2.01 (1.01, 3.98), and infant characteristics and NICU morbidities in another model, RR 2.41 (1.01, 5.75). In both models the confidence intervals are wide (Appendix E, Evidence Table 17).

However, Mestan, 2005,⁵⁶ reporting on the outcome of survivors at two years of age of the Schreiber, 2003 study, described a 47 percent decrease in the risk of cognitive impairment, defined as an MDI < 70 (RR 0.53 (0.29, 0.94)), but no effect on motor impairment, defined as a PDI < 70 (RR 0.73 (0.33, 1.61)). Fewer infants treated with iNO had neurodevelopmental impairment, a composite variable including CP, blindness, hearing loss, and developmental delay, than infants treated with placebo (24 percent versus 46 percent respectively, p-value = 0.01). This difference in the composite outcome was the result of fewer infants with cognitive impairment in the iNO group as there was no difference between the groups in the rate of CP, vision or hearing loss (Appendix E, Evidence Table 17).

Three of the RCTs that gave iNO at 20 ppm or titrated the dose based on response reported long term developmental followup.^{35, 57, 76} Walsh, 2010⁵⁷ found no improvement in function at two years of age among infants treated with iNO in the study of Ballard, 2006.³⁴ Rates of CP, cognitive delay, vision impairment, and hearing impairment were similar between the groups. In 30 month followup of infants enrolled in the Subhedar, 1997,⁶⁴ and Bennett, 2001⁷⁶ studies similar rates of neurodevelopmental delay (MDI or PDI < 85), severe disability (defined as MDI or PDI < 70, or hearing loss or blindness), or death and severe disability were found between iNO treated infants and those receiving standard care. Huddy, 2008³⁵ found no difference at four to five years of age between the groups enrolled in the study of Field, 2005⁶³ in the rates of CP, cognitive delay, vision, and hearing impairment, combined moderate to severe disability, or in those free of impairment (23 percent iNO versus 19 percent placebo) (Appendix E, Evidence Table 17).

No meta-analyses were conducted for dose of iNO and neurodevelopmental impairment as the definition of impairment varied significantly between studies.

In summary, a meta-analysis of studies of 10 ppm dose of iNO found a statistically significant reduction in BPD at 36 weeks PMA but meta-analyses found no statistically significant effect on death, or the combined outcome of death or BPD compared to control. The finding of a statistically significant effect at 10 ppm may be spurious as there is no clinical rationale for why that dose would be different from the others.^{34, 63-66} Results for neurodevelopmental impairment at this dose were inconsistent. There was no statistically significant difference between iNO and control at doses of 5 ppm, 20 ppm or titrating the dose to the patients' response.³⁷

iNO with concurrent therapies. Two studies directly addressed the effect of iNO with concurrent therapies. In a factorial design, Subhedar, 1997⁶⁴ randomized 20 infants to treatment with iNO and dexamethasone and compared their outcome to 22 infants randomized to dexamethasone alone. Dexamethasone was given intravenously every 12 hours for six days at

0.5 mg/kg/dose for six doses, and 0.25 mg/kg/dose for the remaining six doses. All infants were less than 32 weeks gestational age at birth (Appendix E, Evidence Table 17). There was no difference between groups in the risk of death (RR 1.57 (0.76, 3.38)); BPD at 36 weeks PMA, defined as an oxygen requirement beyond 36 weeks PMA and an abnormal chest radiograph (RR 0.79 (0.44, 1.33)); the combined outcome of death or BPD at 36 weeks PMA (RR 1.05 (0.84, 1.25)); or BPD in survivors (RR 1.07 (0.71, 1.37)) (Appendix E, Evidence Table 17).

In a post hoc analysis, Ballard, 2006³⁴ reported that there were no significant differences in response to iNO by exposure to postnatal corticosteroids, though data were not shown. In two year followup, Walsh 2010⁵⁷ found that there was no interaction between iNO treatment and postnatal dexamethasone therapy given > three days after study enrollment compared with dexamethasone given ≤ three days from enrollment in a multivariable model of NDI.

Conclusion

Only two of the 14 randomized controlled trials that reported death, BPD, death or BPD, or neurodevelopmental impairment planned *a priori* to evaluate infants by subgroups,^{58, 64} so the evidence to answer this Key Question is not optimal. There is insufficient evidence to support treatment with iNO for acute lung disease within the first three days after birth. The one trial that compared infants treated at ≤ three days with those treated at four to 28 days found no difference between the groups. Given that none of the 14 RCTs reviewed in Key Question 1 found a significant difference in mortality or survival between those treated with iNO controls, many of which initiated therapy at less than three days, it is likely that early treatment is not beneficial. However, the duration of exposure to iNO varied in the trials and has yet to be systematically studied. For infants with developing BPD, earlier treatment (7 to 14 days) may prove to be more beneficial than later treatment (15 to 21 days) as shown by improved survival without BPD in the Ballard 2006 trial; an RCT with this primary hypothesis needs to be done. It is not surprising that delivery of iNO by high frequency ventilation conferred no convincing benefit, as high frequency ventilation alone has not been shown to reduce mortality, BPD, or improve neurodevelopmental impairment in preterm infants compared to conventional ventilation in systematic review.⁹⁴ The optimal dose of iNO has yet to be determined. Our meta-analysis found a statistically significant effect for 10 ppm for BPD at 36 weeks PMA, but this may be a spurious finding. A similar effect was not seen for death or the composite outcome of death or BPD. Dose may be^{34, 37, 63-66} less important than the duration of iNO exposure, but data are insufficient to make that determination. The effect of concurrent therapies other than postnatal dexamethasone and iNO administration has not been studied in preterm infants.

Chapter 4. Discussion

The most prevalent finding of this report is the lack of effectiveness of iNO in improving survival or decreasing pulmonary morbidity or neurodevelopmental impairment for preterm infants who receive respiratory support. A systematic review of the evidence and meta-analyses revealed no significant difference between preterm infants ≤ 34 weeks gestational age treated with iNO and control infants in the risk for mortality, BPD at 36 weeks PMA, short term risks (PDA, sepsis, NEC, treated ROP, pulmonary hemorrhage, or air leak), brain injury, motor or cognitive impairment, sensory impairments, growth or many other health outcomes.

The most important positive finding of this review is a meta-analysis of pooled data from 11 RCTs that reported the composite outcome of death or BPD at 36 weeks PMA which found a small (7 percent) but statistically significant reduction in the risk with iNO therapy. Power calculations for sample size determination were performed *a priori* for death or BPD or its complement, survival without BPD, in eight of the 11 (73%) trials in the meta-analysis. It has been suggested that the study by Ballard, 2006³⁴ should not be included in meta-analyses as it had a very different study design as well as the lowest mortality rates when compared to the other RCTs. In a sensitivity analysis, removing Ballard, 2006 from this meta-analysis did not change the effect estimate (RR 0.93) but did result in wider confidence interval that included 1. We feel that the meta-analysis with all 11 trials provides a more complete picture of the available evidence, considering the effect of iNO as a continuum of exposure

By analyzing reported outcomes from the 14 RCTs and, where appropriate, other cohort studies, we tried to glean as much evidence as possible of how exposure to iNO influences preterm outcomes. Some statistically significant differences were reported for a few individual RCTs included in this review. Two large trials^{37, 58} reported a statistically significant reduction of brain injury in favor of iNO, and raised hopes that iNO may be neuroprotective. One followup study of a RCT found a statistically significant reduction in cognitive and neurodevelopmental impairment.⁵⁶ One large multicenter trial was stopped early for concern that the iNO group had a higher rate of brain injury,⁴⁰ and on followup at two years, found a statistically significant increase in the rate of CP with iNO compared to the control group. In contrast, a smaller trial in preterm infants with pulmonary hypertension found a reduction in CP rate with iNO³⁸ None of our meta-analyses of these variables found statistically significant effects of iNO exposure, but variability in definitions of outcome variables hindered our ability to aggregate all of the available data and perform meaningful meta-analyses.

Once iNO was found to be an effective treatment for full term and late preterm infants with hypoxemic respiratory failure,⁴ attention turned to using it in more immature preterm infants. Some of the earlier and smaller studies of iNO in preterm infants focused on immediate physiological response to iNO (i.e., improvement in oxygenation index, arterial-alveolar oxygenation ratio, changes in echocardiographic estimates of pulmonary artery pressure) and toxicities, including methemoglobinemia, and pulmonary and intracranial hemorrhages.^{59-61, 64-67} Some early studies started with the iNO dose recommended for full term infants, 20 ppm,^{64, 66, 72} whereas other early studies started at 5 to 10 ppm, and some increased to 20-40 ppm if there was no response.^{60, 63, 65} The majority of the earlier RCTs began weaning iNO within two to six hours.^{60, 61, 64-67} An alternative approach views iNO as a potential growth promoter of the lung and its underlying vascular bed, requiring a longer duration of treatment. Since 2003, four well conducted multicenter RCTs and one single center RCT have published their outcomes for 200 or more infants randomized to receive iNO or placebo gas for one or more weeks.^{34, 37, 40, 58, 62}

Barrington and Finer conducted a systematic review of the evidence for efficacy and toxicities of iNO in preterm infants born before 35 weeks gestation, updated in 2007.³¹ They grouped 11 RCTs into categories based on inclusion criteria: 1) the early routine use of iNO (i.e., RCTs that treated preterm infants on mechanical ventilation in the first three days after birth) found a marginally significant reduction in death or BPD, RR 0.91 (95 percent CI 0.84, 0.99), and, in severe IVH, IPH or PVL, RR 0.70 (CI 0.53, 0.91); 2) early rescue treatment based on oxygenation inclusion criteria found no significant differences in death or BPD but a trend toward increased risk of severe IVH; and 3) enrollment based on increased risk of BPD at four or more days after birth, and there were no statistically significant effects of iNO on mortality or BPD or increase progression of IVH. They were able to report on neurodevelopmental outcomes from only two RCTs.^{56, 76}

The strength of the evidence was graded for all outcomes included in each key question and the results are presented below (Tables 11 to 15). A summary of the meta-analyses completed, by key question and outcome, is provided in Table 16.

Our review differs from the Barrington and Finer Cochrane review³¹ in that there have been three more RCTs published: 1) a small Asian RCT of 65 infants with severe respiratory distress syndrome (Su, 2008⁶⁵), 2) a report of the 29 infants born below 34 weeks gestation but with birth weight above 1500 g from the NICHD Neonatal Research Network (Van Meurs, 2007),³⁹ and 3) a large multicenter trial of 800 infants with gestational ages of 24 to 28 weeks.⁶² In addition, we were charged with a broader mission: to review the data regarding a number of short term risks, long term pulmonary and neurodevelopmental outcomes, outcomes among subpopulations, and the effects of iNO dose, timing, duration, and concurrent therapies on outcomes. By using a broader definition to include outcome at one year corrected for degree of prematurity, and finding more recent outcome studies, including one with outcomes at four to five years, we were able to review long term outcomes for eight RCTs.^{30, 35, 36, 39, 44, 56, 57, 76} The Barrington and Finer Cochrane systematic review³¹ makes a valid point that the studies of iNO in preterm infants vary substantially in their eligibility criteria. The RCTs also vary widely in dose, method, and duration of administration of iNO. But the focus of studying effects of iNO on preterm infants has evolved from immediate pulmonary or cardiovascular effects, to how it may influence the growth and maturation of the developing lung and its cardiovascular support. To provide another perspective, we chose to view the variation in respiratory disease severity, iNO dose, method, and duration of iNO administration as varying degrees of iNO exposure on a continuum of degree of organ maturation, as measured by postmenstrual age. Postmenstrual age is the sum of gestational age at birth and chronological age, and is currently the best measure of preterm maturation that we have. We view brain injury and neurodevelopmental outcomes also in terms of degree of maturation (i.e., PMA) when exposed to iNO. The heterogeneity of our meta-analyses for the composite brain injury variable and for cognitive impairment could be explained by the effect of iNO in the two trials that included preterm infants with birth weights over 1500 g (Schreiber, 2003 and Van Meurs, 2007).^{39, 58} The bigger infants are more likely to be the more mature infants, and may benefit more from iNO effects on pulmonary blood flow because they are better able to autoregulate their cerebral blood flow.

A recent individual patient data meta-analysis has been presented,⁹⁵ but has not yet been published. A synthesis of data on short term outcomes on 3298 preterm infants (< 37 weeks) from 11 trials found no statistically significant differences in death or CLD, RR 0.96 (0.92, 1.01) or in severe neurological abnormalities on neuroimaging, RR 1.12 (0.98, 1.28).⁹⁵ They concluded that there was a lack of evidence to support the “indiscriminate” use of iNO in treating preterm infants with respiratory failure.

The driving force behind the studies of iNO in preterm infants who receive respiratory support is the search for an effective treatment that improves survival and pulmonary health without increasing the risk of adverse short and long term outcomes. As many as one third to one half of the preterm infants enrolled in the studies discussed in this report died in the NICU. Most of the survivors had residual chronic lung disease (BPD) that significantly prolonged their hospitalization and influenced their quality of life after discharge home from the NICU. In the two studies that reported it, only 20 to 40 percent of survivors in both the iNO and control groups had normal neurodevelopmental outcomes at one to two years.^{30, 35, 36} As cohort studies and RCTs of iNO in preterm infants born at or before 34 weeks gestation were being conducted, off label use of iNO in this population dramatically increased. One publication reported a six fold increase in its use between 2000 and 2008 in a large multisite pediatric group.⁴⁷

Whether the small statistically significant reduction of death or BPD we found on meta-analysis is clinically meaningful depends on one’s point of view. When compared to the evidence amassed for the efficacy iNO in treating full term infants and preterm infants born after 34 weeks gestation with respiratory failure, a reduction of death or BPD by less than 10% is very weak. But many parents would grasp at even that small a difference in their sick preterm infant’s chances in surviving without BPD or NDI. We agree with Barrington and Finer in their 2007 Cochrane review³¹ and Askie, 2010 (abstract)⁹⁶ that current evidence does not support the routine use of iNO to treat preterm infants. We do not conclude, however, that we should abandon the possibility that iNO may someday become a component of a treatment strategy for some preterm infants receiving respiratory support. Several factors contribute to our

recommendation to continue the study of iNO: 1) our finding a small but statistically significant difference in death or BPD at 36 weeks PMA, the common primary outcome variable of 73 percent of RCT conducted to date; 2) the statistically significant finding of a diminished need for chronic pulmonary medication at one year corrected age, suggesting less severe lung disease in those treated with iNO, and 3) no studies have been powered to detect meaningful differences in infant functional outcome or quality of life with iNO treatment compared to standard therapy.

Treatment of preterm infants born at or below 34 weeks gestation with iNO should occur only in the context of rigorously conducted RCTs that have the power to detect meaningful long term outcomes. Strategies for treatment need to consider how different preterm infants are from full term infants. Their immature organs are not prepared to support extrauterine life, persistent pulmonary hypertension is not as much of a problem early in the disease process, they lack important natural defenses (e.g., surfactant, cortisol, immune responses), and their response to organ injury seems to vary depending on degree of maturation. Studies of iNO therapy to date have enrolled and treated infants based on gestational age and chronological age, both imperfect measures of maturity. Degree of lung and brain maturation seems to be a very important variable, and treatment should be viewed in terms of postmenstrual age, a construct that better reflects organ maturation. Consideration of postmenstrual age at the time of initiation and duration of iNO therapy may help select subgroups of infants most like to benefit from the therapy. Funded, ongoing basic research into the mechanisms by which iNO may influence the developing lung can provide insight into how to design future clinical trials. Evaluating the effect of iNO on brain injury requires neuroimaging before treatment, as well as on serial studies. BPD at 36 weeks PMA and evidence of brain injury are important mediators. Prolonged hospitalizations, use of supplemental oxygen and pulmonary medications after NICU discharge, prevalence of reactive airway disease and recurrent hospitalizations (as reported by Ballard, 2006³⁴ and Hibbs, 2007⁴⁴) are more important indicators of pulmonary function and health.⁴⁴ Neurodevelopmental outcomes and functional abilities in childhood are far more important outcomes than evidence of brain injury on neuroimaging studies. Careful assessment of the few statistically significant but inconsistent differences with iNO exposure, combined with ongoing basic science and clinical research on the developing lung and brain, their response to and recovery from injury can provide insights that lead to testable hypotheses for future randomized controlled trials.

Chapter 5. Future Research

Future studies on the efficacy of iNO therapy for preterm infants that require respiratory support should have strong conceptual frameworks that test hypotheses on the mechanism by which iNO therapy improves pulmonary or neurodevelopmental outcomes. Such research should measure biomarkers of this mechanism of action, beyond improvement in oxygenation and neuroimaging. Inhaled NO has been given to infants as prophylaxis to prevent the development of BPD, as rescue therapy for respiratory failure, and as treatment in those with evolving BPD. Future studies should postulate and test hypotheses concerning the role of iNO in improving outcomes for any of these conditions or groups of preterm infants.

Bronchopulmonary dysplasia at 36 weeks PMA and intraventricular hemorrhage, intraparenchymal hemorrhage, and periventricular leukomalacia are useful intermediate variables and should be thought of in that context. Although neuroimaging of brain injury can monitor for safety, the more important outcomes for future RCTs are neurodevelopmental outcomes and function in childhood. Standardized tools that measure childhood quality of life and functional outcomes would assess the long term impact of iNO on health and development. Considerations of the frequency of pulmonary rehospitalization, chronic and episodic pulmonary medication, and missed school days would provide a broader context in which to view the efficacy of iNO. Studies should be powered to assess pulmonary, neurodevelopmental, and health outcomes at two to five years or more. Measuring such outcomes will require substantial investment by funders. What follows are considerations for future research.

Other Future Research Needs

Patients

- RCTs must be adequately powered to assess the effect of iNO on subgroups of preterm infants, such as those of varying birth weight.
- Special care must be taken if infants born at the limit of viability are included in randomized controlled trials. These infants do not yet have alveoli (gas exchange occurs through their terminal bronchioles) and their brains do not yet have gyri or sulci. They are most vulnerable to organ injury, which may be most evident on long term followup. Every effort must be taken to obtain pulmonary, neurodevelopmental and health followup for all infants in this category.
- There may be a value to viewing the use of iNO in terms of postmenstrual age, which is a better measure of degree of maturation and takes into account both gestational age and chronologic age in developing preterm infants.

Intervention

- Since the goal is to support pulmonary and brain development in the NICU, courses of iNO given for weeks, not days, should be studied.

- Mode of ventilation should be considered in randomization schemes for trials restricted to infants < 1500 grams, those at highest risk for death, BPD, and neurodevelopmental impairment, to adequately address the question concerning mode of delivery.
- As many of the smallest preterm infants are managed with CPAP or high flow nasal cannula alone, without intubation, information concerning iNO delivery with these devices is needed.

Outcomes

- Future RCTs should require neuroimaging by standardized protocols before trial enrollment, to detect the occurrence and progression of brain injury during iNO treatment.
- Studies should be powered to assess long term neurodevelopmental, pulmonary, and other health outcomes.
- Outcomes should focus on functional status and quality of life, as well as neurodevelopmental disabilities.
- Studies are needed to provide information on resource utilization such as rehospitalizations, medications, physicians' visits. Future focus should be on the real pulmonary problems of prolonged hospitalizations, use of supplemental oxygen, and pulmonary medications after NICU discharge, prevalence of reactive airway disease, and recurrent hospitalizations.
- Consideration should be given to assess longer term childhood outcomes (e.g., pulmonary function tests, school performances).
- Cost benefit analyses should be conducted with multicenter RCTs of iNO.

Appendix A: List of Acronyms

Acronym	Definition
AHRQ	Agency for Healthcare Research and Quality
ArtrCath	Arterial catheter
BPD	Bronchopulmonary dysplasia
BSID	Bayley scale of infant development
BW	Birth weight
CMV	Conventional mechanical ventilation
Congen	Congenital anomaly/malformation
CP	Cerebral palsy
CPAP	Continuous Positive Airway Pressure
DQ	Developmental quotient
Dshunting	Ductal Shunting
ECMO	Extracorporeal membrane oxygenation
EDC	Estimated date of confinement
F/U	Follow- up
FDA	Food and Drug Administration
FiO ₂	Fraction of Inspired Oxygen
g	grams
GA	Gestational age
GCAS	General conceptual ability
HFFI	High-frequency flow interruption
HFOV	High-frequency oscillatory ventilation
HFV	High-frequency ventilation
HRF	Hypoxemic respiratory failure
iNO	inhaled Nitric Oxide
intrprncyml	Intraparenchymal lesion
IPH	intraparenchymal hemorrhage
IQR	Inter-quartile range
IVH	Intraventricular Hemorrhage
JHU	Johns Hopkins University
KG	Kilograms
MAP	Mean airway pressure
MDI	Mental developmental index
mmHg	millimeters of mercury
NDI	Neurodevelopmental impairment
NEC	Necrotizing enterocolitis
NICU	Neonatal intensive care unit
NIH	National Institutes of Health
NO	Nitric oxide
NO ₂	Nitrogen dioxide
OI	Oxygenation Index
Oligho	Oligohydramnios
OMAR	Office of Medical Applications of Research
PDA	Patent Ductus Arteriosus
PDI	Physical developmental index
PMA	post menstrual age
PPHN	Persistent Pulmonary Hypertension of the Newborn
ppm	parts per million
Pulmhyp	Pulmonary hypoplasia
PVL	Periventricular leukomalacia
RCT	Randomized controlled trial
RDS	Respiratory distress syndrome
Respfail	Respiratory failure
ROP	Retinopathy of Prematurity
RX	treatment
SD	Standard deviation
Vent Support	Ventilation Support

Appendix C. Screen and Data Abstraction Forms

Abstract Review Form

The screenshot shows the DistillerSR web application in a Windows Internet Explorer browser. The address bar shows the URL: https://systematic-review.net/Submit/RenderForm.php?id=1&hide_abstract=1. The page title is "DistillerSR". In the top right corner, there is a user menu showing "Project: INO (Switch)", "User: ritu.sharma (My Settings)", and "Messages: 1 new". Below this are buttons for "Live Support" and "User Guide".

The main navigation bar includes: Review, Datarama, Reports, References, Forms, Manage Levels, Users, and Logout.

The form content is as follows:

Refid: 12, Skateboards: Are they really perilous? A retrospective study from a district hospital.
Rethnam U, Yesupalan RS, Sinha A.

and go to or

1. Does this apply to any of the key questions?
Answer questions under exclusion, inclusion, OR unclear below

No (go to "exclusion criteria") Yes (go to "inclusion criteria") Unclear: no abstract, or cannot determine eligibility from abstract alone (retrieve article for full-text screening)

KEY QUESTIONS

1: Does inhaled nitric oxide (INO) therapy increase survival and/or reduce the occurrence or severity of bronchopulmonary dysplasia (BPD) among premature infants who receive respiratory support?
2: Are there short-term risks of INO therapy among premature infants who receive respiratory support?
3: Are there effects of INO therapy on long-term pulmonary and/or neurodevelopmental outcomes among premature infants who receive respiratory support?
4: Does the effect of INO therapy on BPD and/or death or neurodevelopmental impairment vary across subpopulations of premature infants?
5: Does the effect of INO therapy on BPD and/or death or neurodevelopmental impairment vary by timing of initiation, mode of delivery, dose and duration, or concurrent (prostacyclin, phosphodiesterase inhibitors, ductal inhibitors, systemic steroids, surfactant, and vitamin A) therapies?

2. Exclusion Criteria (choose ONE)

No original data (e.g., commentary or review)
 No human data included
 Not written in English and cannot determine eligibility
 Article does not include infants born at less than 34 weeks gestation
 Article does not include pre-term infants who required respiratory support
 Article does not include pre-term infants who were treated with inhaled nitric oxide
 Article does not address any of the Key Questions
 Article address Key Question 1 or 2 ONLY and is not a randomized controlled trial
 Article should be excluded for other reasons

[Clear Response](#)

NOTES ON EXCLUSIONS:
EXCLUDE: ALL letters to the editor
EXCLUDE: ALL articles on near-miss ECMO (ECMO is not used in our group of infants)
EXCLUDE: ALL articles on INO use POST-cardiac surgery. If there is an article on INO pre-cardiac surgery we may want to look at it.
D HERNIA:
Studies on diaphragmatic hernia—read carefully and err on the side of caution. This is a subgroup of infants we may be very interested in.
NO ORIGINAL DATA:
If an article is a review or meta-analysis, please make a note in the comments if you think it is of interest. We will pull it and review references, etc.
Also, ALL article in the Journal, "Pediatric Clinics of North America" are reviews.

3. Inclusion criteria: Abstract should apply to at least one of the key questions (Choose all that apply):

Key Question 1 [MUST be an RCT]
 Key Question 2 [MUST be an RCT]
 Key Question 3
 Key Question 4
 Key Question 5

4. Unclear: No abstract available, or cannot determine eligibility from abstract alone

Unclear-retrieve article for full-text screen

---	--

EXCLUSION NOTES

EXCLUDE: ALL letters to the editor
EXCLUDE: ALL articles on near-miss ECMO (ECMO is not used in our group of infants)
EXCLUDE: ALL articles on iNO use POST-cardiac surgery. If there is an article on iNO pre-cardiac surgery we may want to look at it.
D HERNIA: Studies on diaphragmatic hernia—read carefully and err on the side of caution. This is a subgroup of infants we may be very interested in.
NO ORIGINAL DATA: If an article is a review or meta-analysis, please make a note in the comments if you think it is of interest. We will pull it and review references, etc.
 ALL articles in the journal, "Pediatric Clinics of North America" are reviews.

OTHER NOTES:
Case Reports: we are NOT excluding case reports solely base on study design.
Letters to the editor: after discussion with Karen and the Sr. Team members, we decided to change our initial blanket exclusion criteria for letters for the following reasons: as in case reports we are not excluding articles based solely on study design (or publication type); in some instances, there is usable data in a letter.
iNO use in transport: There are some articles that discuss iNO use in transport in critically ill patients—read the abstract/article carefully. We may need to include these—err on the side of caution.
Short-term outcomes: we are not including articles addressing only short-term outcomes—EXCEPT for length of time on O2, length of time on ventilator, and death.
PMA: A lot of studies have study groups including patients <34 weeks PMA, but these subjects are mixed in with patients of other ages that do not fall within our criteria—if the data on patients < 34 weeks OPMA is not stratified, we cannot use the study **NOTE: LOOK at the study not just the tables to make sure that there is not some stratified data we can use.**
If a team member has a specific interest in a short-term outcome of iNO and notices some papers they are interested in, they can keep a log of the articles and the core team will gather these articles when time allows for the individual team member's use.

---	---

General Outcomes

13.

- Death
- Survival

Cardiac/Infectious Disease/Gastrointestinal Outcomes

14.

- Methemoglobinemia
- Necrotizing Enterocolitis (NEC)
- Patent Ductus Arteriosus (PDA)
- Sepsis

Pulmonary Outcomes

15.

- Air leak
- Bronchopulmonary Dysplasia (BPD)
- Severe Bronchopulmonary Dysplasia--vent dependant BPD
- Chronic Lung Disease
- Hospital Discharge / Readmission
- Pulmonary Function Test (PFT)
- Pulmonary Hypertension
- Pulmonary hemorrhage
- Right heart disease--diagosed by echocardiogram
- Respiratory Medications
- Tracheostomy
- Other

Neurodevelopmental Outcomes

16.

- Bayley Scale of Infant Development
- Behavioral problems
- Cerebral Palsy (CP)
- Griffith Scale
- Growth
- Hearing Impairment
- Hydrocephalus--requiring medical treatment
- Periventricular Leukomalacia (PVL)
- Retinopathy of prematurity (ROP) requiring treatment by cryo or laser
- Seizures / Fits
- School readiness and behavioral impairment
- Ventriculomegaly
- Visual Impairment
- White Matter Injury

Risk of Bias Assessment (Case Controls)

Selection

1. Is the case definition adequate?

- Yes, with pathophysiological measure
- Yes, with diagnosis but no pathophysiological measure
- No description

Clear Response

2. Representativeness of the cases

- All eligible cases with outcome of interest over a defined period of time OR all cases in a defined geographical area (e.g. New England, Western Ontario, etc.) OR all cases in a defined hospital or clinic, group of hospitals, he
- Not satisfying requirements in part (a), or not stated.
- Unclear

Clear Response

3. Selection of Controls

- From same NICUs as cases
- From different NICUs
- No description

Clear Response

4. Definition of Controls

- No history of treatment (endpoint)
- No description of source
- Unclear

Clear Response

Comparability

5. Comparability of cases and controls on the basis of the design or analysis

- Study controls for birth weight
- Study controls for sex
- Study controls for gestational age
- Study controls for prenatal steroid usage
- Study controls for other

Exposure

6. Ascertainment of treatment group

- Medical records
- No description
- Unclear

Clear Response

7. Same method of selection of treated patients for cases and controls

- Yes
- No
- Unclear

Clear Response

Risk of Bias Assessment (Cohort Studies)

Selection

1. Representativeness of the treated cohort

- Truly representative of the stated study population
- Somewhat representative of the stated study population
- No description of the derivation of the cohort
- Comment

[Clear Response](#)

2. Selection of the control cohort (*Skip to question 3 if there is no control group*)

- Selected from same NICU or group of NICUs
- Drawn from a different source
- No description of the derivation of the control cohort

[Clear Response](#)

3. Selection of treated patients

- Medical record
- Other
- No description

[Clear Response](#)

4. Demonstration that outcome of interest was not present at start of study

- Yes
- No
- Unclear

[Clear Response](#)

Comparability

5. Comparability of cohorts on the basis of the design or analysis (*Skip to question 6 if there is no control group*)

- Yes
- No
- Unclear

[Clear Response](#)

Outcome

6. Assessment of outcome

- Independent blind assessment
- Record linkage (e.g. identified through ICD codes on database records)
- Parent report
- Teacher report
- No description

[Clear Response](#)

7. Was follow-up long enough for outcomes to occur? (*Judgment Criteria*)

- Yes
- Yes for at least 1 outcome of interest
- No
- Unclear

[Clear Response](#)

8. Were incomplete outcome data adequately addressed? (*Judgment Criteria*)

- Yes
- No
- Unclear

[Clear Response](#)

Hamon, 2005 ¹³		28 days	Control Hypoxemic Respiratory Failure, no iNO	39	27 (69.3)					
			iNO treated Hypoxemic Respiratory Failure	37	22 (59.5)					
Mestan, 2005 ²²		25.2+/-8.4 months	Control	102	79 (78)					

Evidence Table 17. All outcomes addressed in the KQ5 subgroups including death, BPD, and NDI (continued)

Author, Year	Outcome	Time of outcome measure	Study Arm	N (number of participants measured)	Participants with Outcome— n (%)	Relative Effect (95% CI)	Adjusted Relative Effect (95% CI)	Adjustments	Duration	Difference in Duration (p-value)		
		corrected age										
Schreiber, 2003 ⁸	Survived NICU		Control	102	79 (77.5)							
			iNO	105	89 (84.8)							
Ballard, 2006 ¹	Survival without BPD	36 weeks PMA	Control	288	105 (36.5)	p-value:0.04 RR: 1.26 (1.02-1.55)	RR: 1.45 (1.03-2.04)	cluster (multiple s) using GEE; from the letter to the editor correction				
			iNO	294	129 (43.9)							
			Control 7-14 days age at study entry	115	31 (27)	RR: 1.91 (1.31-2.78)						
			iNO 7-14 days age at study entry	112	55 (49.1)							
			Control 15-21 days age at study entry	173	74 (42.8)	RR: 0.99 (0.77-1.28)						
			iNO 15-21 days age at study entry	182	74 (40.7)							
Hamon, 2005 ¹³	28 days		Control	39	12 (31)							
			iNO	37	14 (38)							

Evidence Table 17. All outcomes addressed in the KQ5 subgroups including death, BPD, and NDI (continued)

Author, Year	Outcome	Time of outcome measure	Study Arm	N (number of participants measured)	Participants with Outcome— n (%)	Relative Effect (95% CI)	Adjusted Relative Effect (95% CI)	Adjustments	Duration	Difference in Duration (p-value)
Bennett, 2001 ¹⁵	Severe neurodisability - one or more of: moderate or severe developmental delay; CP; sensorineural impairment (hearing loss requiring hearing aids and blindness)	30 months corrected age	Control	14	5 (36)	P-value: 0.12				
			iNO	7	0 (0)					
Field, 2005 ³	Severe disability defined as no /little head control or inability to sit unsupported or no/minimal response to visual stim (equivalent to DQ <50 age	1 year corrected age	Control	18	2 (11)					
			iNO	25	7 (28)					

Evidence Table 17. All outcomes addressed in the KQ5 subgroups including death, BPD, and NDI (continued)

Author, Year	Outcome (adjusted)	Time of outcome measure	Study Arm	N (number of participants measured)	Participants with Outcome— n (%)	Relative Effect (95% CI)	Adjusted Relative Effect (95% CI)	Adjustments	Duration	Difference in Duration (p-value)
Hintz SR, 2007 ¹⁷	NDI: any of the following: mod-severe CP, blind, deaf, MDI<70 or PDI<70	18-22 months	Control	102	48 (47)	P-value:0.74 RR: 1.07 (0.80 - 1.44)				
			iNO	89	45 (51)					
Huddy, 2008 ¹⁸	Moderate or severe cognitive disability (GCAS<70)	4-5 yrs, median 4.52 (IQR 0.9)	Control	16	6 (37.5)					
			iNO	22	6 (27.3)					
	Moderate / Severe CP	4-5 years	Control	16	2 (12.5)					
			iNO	22	3 (13.6)					
Mestan, 2005 ²²	Abnormal neurodevelopmental outcome (any disability or any BSID II score <70)	25.2+/-8.4 months corrected age 24.9 +/- 7.9 months corrected age	Control	68	31 (46)	P-value:0.01 RR: 0.53 (0.33-0.87)				
			iNO	70	17 (24)					
Van Meurs, 2007 ¹¹	NDI = any one of the following: moderate to severe CP, blind,	18 to 22 months	Control	8	2 (25)					
			iNO	9	1 (11)					

Evidence Table 17. All outcomes addressed in the KQ5 subgroups including death, BPD, and NDI (continued)

Author, Year	Outcome	Time of outcome measure	Study Arm	N (number of participants measured)	Participants with Outcome— n (%)	Relative Effect (95% CI)	Adjusted Relative Effect (95% CI)	Adjustments	Duration	Difference in Duration (p-value)
	deaf, MDI <70, or PDI <70									
Walsh, 2010 ²⁰	NDI in subset with complete evaluations	2 years	Control	212	(51)	RR:0.93 (0.76-1.14)				
			iNO	207	(48)					
	Neurodevelopmental Impairment (NDI = MDI<70, PDI<70, unable to crawl or walk (GMFCS>=2), bilateral blindness, or bilateral deafness requiring amplification).	2 years	Control	234	114 (49)	RR: 0.92 (0.75-1.12)				
			iNO	243	109 (44.8)					
	Moderate / Severe CP	2 years	Control	234	12 (5.1)	RR: 1.23 (0.59-2.55)				
			iNO	243	12 (4.9)					
Watson, 2009 ²¹	NDI (CP, severe hearing loss, MDI	1 year corrected age	Control	218	73 (33.5)	P-value: 0.66				
			iNO	237	84 (35.4)					

Evidence Table 17. All outcomes addressed in the KQ5 subgroups including death, BPD, and NDI (continued)
